The a-c system is assumed to supply a sinusoidal voltage of fundamental frequency to which are added two 3rd harmonic components, $E_n$ and $E_r$. The segments $S_1$ and $S_2$ of the rectifier are assumed connected in some manner with an active d-c system such as a d-c generator driven by an a-c motor supplied from a system capable of giving or receiving power. The rectifier rotor and the generator introducing the harmonics $E_n$ and $E_r$ are synchronously driven from the a-c supply either by individual motors or by a single motor. The sequence of connections among transformer, condenser, d-c terminals and short-circuit is indicated by $a$, $b$, $c$ and $d$ of Fig. 1. Connections $a$ and $d$ correspond to the positive and negative "working" periods respectively

and connections *b* and *c* to the intermediate commutation period.

Fig. 2 is drawn to show the variation of the several voltage and current components previously mentioned. These components are all laid down on a percentage basis and result from the calculations of a hypothetical problem referred to later. The figure represents the case of nominal load rectification. The currents plotted are indicated by symbols corresponding to the points of measurement of Fig. 1e.

The fundamental sinusoidal voltage supplied by the a-c system $E_1$ is taken as 80 per cent, the total a-c system reactance having been assumed as 20 per cent. A single half wave of the reversing voltage $E_r$ is shown in its proper phase. The same is done for the neutralizing voltage $E_n$. The sum of all the voltages supplied from the generating sources is shown as $E$. It will appear that negative values of $E$ predominate during the commutation period 3-4. It is this excess of negative voltage that is instrumental in causing the current in the a-c system to reverse when the transformer is short-circuited.

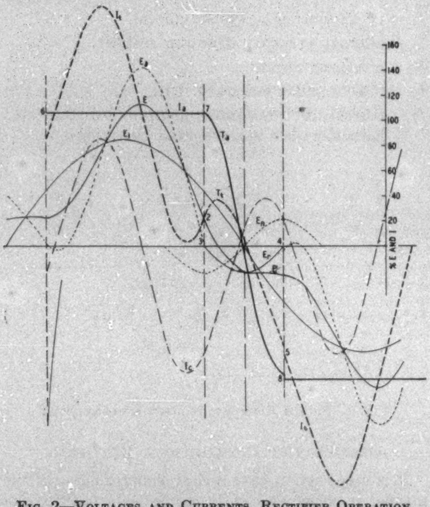

FIG. 2—VOLTAGES AND CURRENTS, RECTIFIER OPERATION

The fundamental condenser current $I_{c1}$ (not shown in the figure) is calculated by using the fundamental voltage $E_1$, the fundamental frequency reactance of the a-c system, and the capacitive reactance of the condenser. The inductive reactance used includes the transformer leakage reactance and the transient reactances of the fundamental and harmonic generators. All resistances are ignored.

The 3rd harmonic condenser current $I_{c3}$ is calculated from the resultant of $E_n$ and $E_r$ and the triple frequency reactance of the *L-C* circuit. The condenser capacitance must be small enough to make this current leading.

$I_c$ represents the total resultant condenser current and is plotted as a steady-state function across the short-circuit period in order to indicate its form when uninterrupted by that period.

For the purpose of this discussion, the alternating current to the rectifier $I_a$ is assumed constant during the working period. Experiments have shown that this current makes a "transit" or reversal from positive to negative along a path (7 to 8, Fig. 2). This indicates that the current transfers occurring under the brushes are gradual and do not result in excessive momentary densities. The current $I_a$ can be caused to remain constant during the working cycle by using a high value of steadying reactance in the d-c circuit. When no reactance is used, this current follows the d-c voltage form.

The current in the transformer coil $I_t$ must necessarily be the sum of $I_a$ and $I_c$. When this is plotted for two successive working periods, it becomes apparent that the net transit required during the commutation period is reduced from 7-8 to 2-5 in the figure. When the transformer is short-circuited, the a-c system current changes under the influence of three electromotive forces $E_1$, $E_n$ and $E_r$. The first two, acting in opposite directions during the short-circuit period and passing through zero at the neutral axis, cause a positive pulse in the current curve. $E_r$ causes a rate of decrease of the current which is a sine function of time. The portion of the $I_t$ curve within the commutation limits is termed the "transit" of $I_t$ and is marked $T_t$ in the figure.

The a-c terminal voltage $E_a$ which exists across the transformer, condenser, and rectifier simultaneously is obtained by adding to the values of $E$ from the generating sources the instantaneous values of $- L \frac{di_e}{dt}$ where $L$ is the inductance corresponding to the total a-c system reactance. It should be noted that $E_a$ may be caused to pass through zero at the points 3 and 4 so that the commutation period is entered and left without voltage and therefore without shock.

## OPERATION OF ELEMENT AS AN INVERTER

The element, the rectifying action of which has just been described and illustrated by Fig. 2, will act as an inverter if the d-c voltage $E_d$ is raised above the corresponding a-c voltage $E_a$ or if $E_a$ is lowered when $E_d$ remains constant. When inversion takes place, there will occur a reversal of the direct current $I_d$ and of the phase of the alternating current $I_a$. The phase of the 3rd harmonic commutating voltage $E_r$ must also reverse and be proportional to the load current transmitted. This proportionality and phase reversal is secured by having the field of the generator furnishing $E_r$ connected in series with the d-c line carrying $I_d$.

Fig. 3, for the case of inversion, has been drawn from values calculated for the hypothetical problem. The operating conditions are the same as for the case represented by Fig. 2 except that the reversals mentioned in the preceding paragraph have taken place. Since the phase of $I_a$ is now opposed to that of $E_1$, the flow of power has reversed. A comparative study of Figs. 2 and 3 will reveal a perfectly symmetrical correspondence between the various voltage and current forms for the two cases of operation. These forms undergo a gradual transition when the load changes as is shown by oscillographic records of Fig. 12.

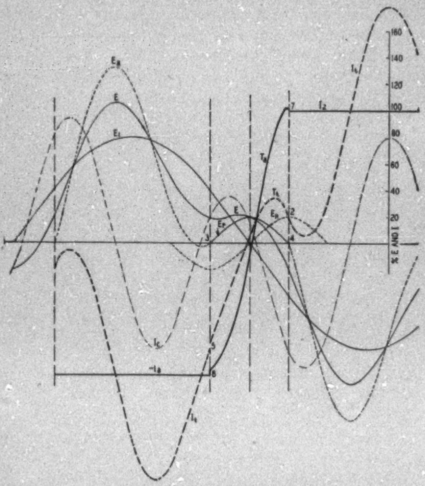

FIG. 3—VOLTAGES AND CURRENTS, INVERTER OPERATION

When the load on the apparatus is zero (neither rectifying nor inverting) which condition obtains when there is a perfect balance of a-c and d-c voltages, the transformer current ($I_t$) will consist of the steady-state condenser current modified by certain surges during the short-circuit period.

## THREE-PHASE APPLICATION

Three or more elements of this rectifier-inverter may be caused to operate in series by the use of a rotor arrangement such as shown in Fig. 4. The contact segments ($S_1$ to $S_4$) are so arranged as to permit one of the intermediate segments $S_2$ to function on two a-c phases so that the number of segment disks will be one more than the number of phases. The connections of the transformers, condensers and twin brush sets are shown by the figure. The d-c lines $D_1$ and $D_2$ may be caused to contact with the terminal segments by means of additional brushes sliding on the latter. This rotor construction will be roughly balanced statically but not dynamically. The four-pole arrangement of such a rotor would be well balanced dynamically.

When a rotor of the above description operates from a three-phase supply, the result is the orderly insertion of the individual transformer secondaries $T_1$, $T_2$ and $T_3$ into the d-c circuit, their withdrawal by short-circuit during the period of reversal, and their reinsertion in reversed sense thereafter. The average d-c voltage will thus be determinable from a knowledge of the contributions by each of the phase voltages. Sufficient reactance placed in the d-c line to filter out the ripples will result in a sensibly constant direct current for either direction of operation.

## COMPLETE EQUIPMENT

A complement of equipment for three-phase a-c to d-c conversion or vice versa is shown in Fig. 5 in which $G$ represents the a-c generating source supplying a bank of transformers with their low-tension coils star connected and their high-tension coils leading to the condensers and the rectifier brushes. The armature of a 3rd harmonic generator $A_h$ is connected into the neutral of the power system. This generator is driven by a synchronous motor $M$ and has two field coils producing two voltage components relatively in quadrature in $A_h$. The field $F_r$, in series with the d-c output of the rectifier, furnishes the reversing component $E_r$. This field may be shunted by $S$ to obtain adjustment in the value of $E_r$. At nominal load, the field $F_r$ must cause low magnetic saturation so as to be able to maintain approximate proportionality between $E_r$ and load current up to the value found on short circuit. The field $F_n$ supplying the

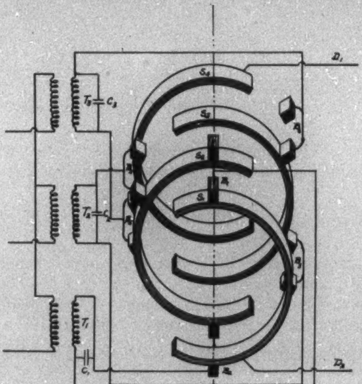

FIG. 4—THREE-PHASE ROTOR, PHASES IN SERIES

neutralizing voltage $E_n$ should be excited in proportion to the a-c system voltage. A mercury-arc rectifying equipment is shown as a convenient way of accomplishing this result. The strength of this field is a maximum at no-load and approaches zero on short circuit.

Transformer taps permit the regulation of the a-c voltage delivered to the rectifier without the necessity of disturbing the system voltage; by means of these, the flow of power may be arbitrarily controlled. Without transformer ratio adjustment, the power flow will automatically vary with the relative voltage levels on the d-c and a-c sides of the apparatus.

### THE REVERSING VOLTAGE $E_r$

A simple equation for the maximum value of the 3rd harmonic commutating or reversing voltage $E_r$ has been derived. The current change in the a-c system when short-circuited during commutation is given by

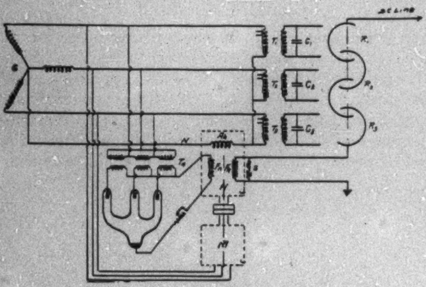

FIG. 5—COMPLETE SYSTEM, RECTIFIER-INVERTER

$$\Delta i = \frac{E_r}{w_3L}\int_0^{\pi} \sin w_3t \, dw_3t = \frac{2}{w_3L} E_r^* \qquad (1)$$

Reference to Fig. 2 will show that the actual change of current to be caused by $E_r$ is from point 2 to point 4 which amounts to $2\,I_d - 2\,I_r$ where $I_r$ is the maximum of the 3rd harmonic condenser current caused by $E_r$. Equating these two values of $\Delta i$ and remembering that $I_r = Y_3E_r$, $Y_3$ being the triple frequency admittance of the $L$-$C$ circuit, there is found

$$E_r = \frac{I_a\,(= I_d)}{\dfrac{1}{w_3L} + Y_3} \qquad (2)$$

From equation (2) it is seen that $E_r$ must be proportional to the load current and that its value is affected by the constants of the equivalent $L$-$C$ circuit considered to exist between the condenser and the a-c system reactance. This equation has yielded correct values of $E_r$ for a large number of experimental circuits.

### THE NEUTRALIZING VOLTAGE $E_n$

Fig. 6 shows a commutation period with the relative phase positions of the three voltages $E_1$, $E_n$ and $E_r$ acting within the short-circuited a-c system. The lines $S'S'$ and $F'F'$ represent respectively the beginning and the end of the short-circuit period when this is taken as covering 60 fundamental degrees. The lines $SS$ and $FF$ indicate the same limits for a shorter period. Each of the voltages produces a leading current component. These components are designated similarly as $I_1$, $I_n$ and $I_r$ and are shown dotted.

$E_n$ should have such a value as to make the terminal voltage across the condenser zero at the time when the short-circuit period is entered and left. The proper value for $E_n$ may be found by equating all the voltages acting in the circuit at these times to zero and solving for $E_n$. Assuming the 60-degree period, all the voltages acting at the beginning of short-circuit may be written as follows:

$$\left.\begin{array}{lll} -L\dfrac{di_1}{dt} = w_1L\dfrac{E_1}{X_1}\cos 60\text{ deg} & & \\ & & \text{(positive)} \\ -L\dfrac{di_r}{dt} = 0 & & \\ -L\dfrac{di_n}{dt} = -\,w_3L\dfrac{E_n}{X_3}\cos 0 & & \\ \qquad (= E_n \text{ approx.}) & & \text{(negative)} \\ e_1 = E_1 \sin 30\text{ deg} & & \text{(positive)} \\ e_r = 0 & & \\ e_n = -\,E_n & & \text{(negative)} \end{array}\right\} \Sigma = 0 \qquad (3)$$

so that

$$-\,E_n = 1/2\left(e_1 + L\frac{di_1}{dt}\right) \qquad (4)$$

Neglecting the term $L\dfrac{di_1}{dt}$ as relatively small, $E_n$ is found to be half of the value of fundamental voltage occurring at the beginning of commutation. Since both the terms $e_1$ and $L\dfrac{di_1}{dt}$ are proportional to the fundamental voltage $E_1$ it follows that $E_n$ should be proportional to the a-c system voltage at the rectifier.

When the commutation period is assumed to be shorter than 60 degrees, the six terms in equation (3) enter into the determination of the value of $E_n$; the result obtained is more complicated and the variation of $E_r$ with load less satisfactory. The solution is possible, however, and has been worked out for such periods.

### POWER TRANSFERS ON MOTOR-GENERATOR SET

The generator armature injecting the harmonic voltages into the neutral carries a current the greater part of which is in quadrature with the resultant induced voltage. Careful analysis has shown that there exists one component of this current that is in strict phase opposition with $E_r$ and is of the same frequency. This component is derived from the transit $T_t$ of Fig. 2. The commutation periods of the three phases are adjacent to each other in point of time so that the pulses or surges of successive transits give rise to alternately positive and negative half-waves of current in the neutral. For rectifier action, these current waves are in phase opposition to $E_r$ so that their interaction represents negative electrical power. In other words, the armature $A_h$ of Fig. 5 is motoring. Space does not permit the presentation of the analysis to show that this power transfer is the only one occurring.[5]

---

*Maximum amplitudes of voltages and currents are assumed throughout this discussion.

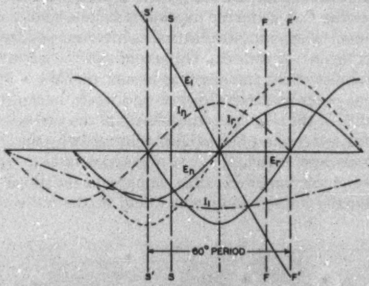

FIG. 6—PHASE RELATIONS OF HARMONIC VOLTAGES AND CURRENTS

The maximum of the pulse in the transit $T_t$ may be found from the equation

$$H_t = \frac{E_1}{\omega_1 L}\int_0^{\frac{\pi}{6}} \sin \omega_1 t\, d\omega_1 t - \frac{E_n}{\omega_3 L}\int_{\frac{\pi}{2}}^{0} \sin \omega_3 t\, d\omega_3 t \quad (5)$$

Since $H_t$ represents the maximum of a sine function, the average power transfer is given by

$$P_{av} = -\frac{1}{2} H_t E_r \quad (6)$$

When the apparatus is inverting, the phase of $E_r$ reverses while that of the 3rd harmonic current in the neutral resulting from the transits does not, so that the armature of the harmonic machine is now generating.

From the solution of a hypothetical problem representing the case of a practical installation of high kva capacity, the power transfer required of the motor-generator set at nominal load proved to be about 1.7 per cent of nominal rating. The maximum power demand occurring at 2.5 times nominal load was about 50 per cent greater or 2.55 per cent.

## RATINGS OF THE MOTOR-GENERATOR SET

The nominal *rating of the motor* would need to be the above mentioned 1.7 per cent of nominal kva of the rectifier-inverter. This motor should be designed generously, however, so as to enable it to meet its maximum demand of 2.55 per cent under the condition of considerably reduced voltage. On short-circuit of the rectifier d-c terminals, the power interchange becomes practically zero (since $E_1 = E_n = 0$).

The generator armature of the motor-generator set carries the triple frequency condenser current caused by the voltages $E_n$ and $E_r$ which, in the case of the problem, resulted in a current of 153 per cent of nominal d-c rectifier current. The voltages $E_n$ and $E_r$ were each 20 per cent at nominal load making a resultant of 28.2 per cent so that the single-phase rating of the generator is approximately 18 per cent of the nominal rating of the rectifier. It appears that about 20 per cent of auxiliary machine capacity (motor and generator) is needed to make this scheme of rectification and inversion successfully operative. Comparing the conventional polyphase a-c system with this one, the percentage kva of auxiliary apparatus such as synchronous condensers required by the former increases with the power transmitted over a given line and the distance while, in the latter, the percentage capacity of auxiliaries does not increase with these factors but decreases with the kva of generating capacity behind the rectifier-inverter.

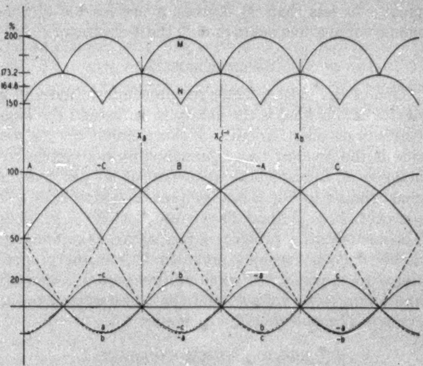

FIG. 7—DIRECT-CURRENT VOLTAGE FORMS

*A*, *B* and *C*—fundamental emf's after rectification
*a*, *b* and *c*—3rd harmonic emf's after rectification
*M*—ideal d-c voltage form
*N*—actual d-c voltage form (dotted components eliminated)

## VOLTAGE FORMS AND RATIOS

The wave form of the a-c voltage used in this apparatus is seen to be peaked sharply by the effect of the 3rd harmonic $E_n$, and somewhat distorted by the harmonic $E_r$. This form is advantageous to the rectifier in that the maximum strain occurs when the brushes are far removed from the segment tips and the rate of increase of voltage is moderate at the borders of the commutation period.

The normal form of the d-c voltage shows a constant value modified by convex ripples which have the form of a half wave of a 3rd harmonic. This form is common with other types of rectifier. If all the voltage values of the three sinusoidal fundamentals could be utilized, the d-c voltage would be represented by the curve *M* of Fig. 7 the values of which vary between 200 per cent and 173.2 per cent of a fundamental maximum. When all voltage values within 30 degrees of zero of each wave are sacrificed to a short-circuit or commutation period as indicated by the dotted parts of the fundamental rectified waves shown in the lower part of the figure, the d-c voltage *N* will vary between 173.2 per cent and 150 per cent, yielding an average value of 164.8 per cent. This figure may be taken as the normal d-c to a-c voltage ratio of the rectifier-inverter.

If the negative 3rd harmonic, in phase, is considered as included in each phase-voltage and the portions deleted by the commutation period shown dotted in Fig. 7 are ignored, it appears that no contribution to the d-c voltage is made by the harmonics. This relationship holds for the harmonic in any phase position with respect to the fundamental. For a commutation period greater or less than 60 degrees, a net residue of harmonic voltage does act to modify the d-c voltage.

## SHORT CIRCUITS

One of the most difficult requirements to meet in a device of this kind is the ability to withstand the high currents on short circuit. A short circuit on the d-c side is the severest test. Assuming an a-c system reactance at fundamental frequency of 20 per cent, a chart similar to Fig. 2 has been made, taking $I_d = 500$ per cent, $E_r = 5$ times 20 per cent, and $E_1 = E_n = 0$. The commutation problem is here solved as completely as for nominal currents provided $E_r$ remains proportional to the load, the commutation period is entered and left at zero voltage, and the transformer current curve has become roughly triangular.

## CHANGE OF SYSTEM CONSTANT *L*

Since the inductance corresponding to total a-c system reactance is a factor determining the 3rd harmonic commutating voltage $E_r$, the change of this constant caused by switching lines, generators or other machines might cause some concern about the ability of the rectifier to commutate properly after such change. The case of a generating plant with four similar units was assumed. Typical values for the transient reactances per phase of the generators and of the leakage reactances of the transformers were used.[6,7] It was found that $E_r$ varies but 10 per cent between the cases of one and of four generators in operation. Experience with the experimental apparatus has shown that a 10 per cent error in the value of $E_r$ produces slight and harmless changes in the forms of the transits.

## APPLICATION TO D-C TRANSMISSION

In setting up a d-c transmission system using this rectifier-inverter, one of the units operating as a rectifier would be supplied through its bank of raising transformers from an a-c system *A*. The d-c line including the harmonic-generator field would be grounded. The other d-c terminal would lead to the single-wire transmission line. Two commutators each operating between ground and line, but of opposite polarity, would be preferable. This would result in a two-wire transmission and eliminate the ground as a conductor. The receiving end of the d-c line would have a similar complement of commutators acting as inverters and feeding into the a-c system *B*. On account of the perfect reversibility of the transforming means, the flow of power might occur in either direction and would be under the control of the relative voltage levels of the two systems. These levels could be modified arbitrarily by the transformer-ratio switches. If two conductors of a typical three-phase line were thus employed, the third and nominally unused conductor would be the full equivalent of a spare circuit. The frequencies maintained by systems *A* and *B* would be of no concern in the operation of this system, there would be no problem of stability, nor would there be any closely defined power limit.

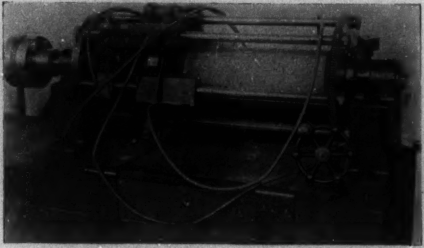

FIG. 8—RECTIFIER-INVERTER FOR THREE-PHASE D-C OPERATION

These rectifier-inverter units seem well adapted to parallel operation since all the commutators function in step. The load distribution as between units would be largely controlled by the transformer leakage reactances. A d-c network might well be established to which certain rectifying units would deliver power and from which other inverting units would take power to be transformed into polyphase a-c power for a local system which, however, should supply its own excitation and fix its own frequency.

## USE AS A FREQUENCY-CHANGER

Two commutators of this type, driven by separate synchronous motors, might serve as a frequency-changing tie between, say, a 60- and a 25-cycle system. The capital cost of such a tie should be much smaller than that of the frequency-changing units now in use in which the power flow must undergo two electromechanical transformations.

## HYPOTHETICAL DESIGN

In order to provide practical checks on the possibilities and limitations of this apparatus as applied to rectification and inversion for the purpose of d-c transmission, an actual design problem has been worked out in parallel with the theory evolved. The assumption has been made that each element of the rectifier would be able to withstand what will no doubt appear to the reader as an impossibly high voltage as but three elements were assumed. The voltage per element may be reduced by going to six, twelve or more elements in series, with a sacrifice in simplicity. The conduct of this design will not be described in detail but the assumptions, data and results are listed below. The size of the equipment was chosen to correspond approximately to the safe capacity of a present-day 250-mile, 220-kv, three-phase line. Two equipments are supposed to operate in series to supply a two-conductor d-c circuit. The results obtained refer to one of these equipments.

*Data Assumed*

D-c rating per rectifier = 375 amp, 144.5 kv, 54,150 kw

D-c rating of pair in series = 375 amp, 289 kv, 108,300 kw

A-c system 60 cycle reactance = 20 per cent ($L$ = 0.086 h)

A-c voltage at rectifier at zero load = 100 per cent

A-c voltage at rectifier on short-circuit = 0

Direct current on short circuit = 500 per cent

Commutation period = 60 deg (fundamental)

100 per cent voltage = $E$ (max.) = 87.7 kv

100 per cent current = 375 amp

*Results Derived*

Normal ratio total d-c volts/$E_1$ (max.) = 1.648

Capacity per condenser = 4.675 $\mu$f at 114 kv (max.)

Total rating based on effective values = 48,700 kva

Rating of transformers

$$\left.\begin{array}{l}\text{Voltages} = 13.2\text{ kv}/62\text{ kv} \\ \text{Current} = 375\text{ amp (ht)}\end{array}\right\} \begin{array}{l}\text{kva} = 23{,}250 \\ (69{,}750\text{ kva, total})\end{array}$$

Ratings of motor-generator set

Motor = 956 kw at unity pf = 1.77 per cent

Generator voltage = 28.2 per cent = 17,500 v

Current = 3 × $I_{c3}$ = 575 amp

Kva = 10,050 = 18.5 per cent

Table I gives the variations of $E_1$, $E_r$, $E_n$ and power transfer in the harmonic motor-generator set for loads varying from zero to 500 per cent (short-circuit) for the case of rectification. Table II shows the variations of the same quantities for the case of inversion on the assumption that $E_1$ again varies from 100 per cent at zero load to zero on short circuit.

TABLE I—POWER TRANSFERS—RECTIFICATION

| % Load | % $E_1$ | $E_r$(%) | $E_n$(%) | Power transfer in kw |
|---|---|---|---|---|
| 0 | 100 | 0 | 25 | 0 |

## CONSTRUCTION OF EXPERIMENTAL MACHINE

An experimental rectifier-inverter was built and tested in the laboratory at Lehigh University. This apparatus, shown in Fig. 8, comprises four canvas-base Formica disks, 6.5 inches in diameter and 0.75 inches wide, carrying the contacting segments. The twin brush sets mounted on fiber blocks may be shifted angularly by a worm gear. The brushes are of laminated copper, providing a contact area 0.75 in. by 0.5 in. Two extra brushes in parallel riding on each of the two terminal disks serve as connections to the d-c lines. The rectifier is run by a two-pole self-synchronizing three-phase motor. The segment group measures eight inches in axial length. The brush rigging is built to accommodate additional segment disks for six-phase operation.

## AUXILIARY APPARATUS

A special General Electric harmonic motor-generator set was used to supply the three-phase power. The fundamental frequency generator served to operate the rectifier motor and to supply power to the transformers as in Fig. 5. One phase of the 3rd harmonic machine of this set injected the voltage $E_r$ into the neutral. The field of this machine was connected in series with the d-c circuit of the rectifier and was adjusted by an inductive shunt. The harmonic voltage $E_n$ was introduced into the neutral by a second 180-cycle generator connected to the main set. The field of this was excited in shunt from the d-c rectifier voltage when this was not too high. Equal reactances were connected into each of the a-c supply lines and adjusted for a drop of 20 per cent at nominal load (5 amp).

A 250-volt and a 1,500-volt motor-driven d-c generator were used at different times as a d-c system for the purpose of loading. Sudden changes of d-c system voltage for the purpose of causing transient reversal from rectification to inversion were produced by switching resistance in and out of the d-c generator field. A high steadying reactance in the d-c circuit made possible a direct current practically free of ripples.

## Experimental Results

The oscillograms of Fig. 9 show the operation as a *rectifier* with a d-c voltage of about 150. The symbols naming the various traces have the meaning attached to them in the earlier parts of the paper. It will be interesting to compare the wave forms of this figure with those predetermined for different conditions shown in Fig. 2. It will be noted that the d-c voltage, the transformer current and the rectifier current are in phase.

Fig. 10 shows similarly the operation as an *inverter*. The a-c voltage and current are now in phase opposition. These curves demonstrate the manner in which the a-c system current-form results from the combination of the steady current from the inverter and the condenser current.

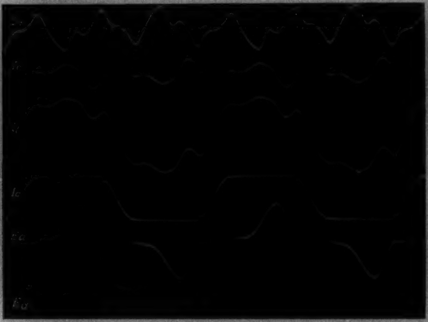

Fig. 9—Oscillograms of Rectifier Operation With High Steadying Reactance in the D-C Circuit

$I_n$—Neutral current
$I_c$—Condenser current
$I_t$—Transformer current
$I_a$—Rectifier (a-c) current
$E_a$—Rectifier a-c voltage
$E_d$—D-c voltage

Fig. 11 shows zero load operation. The surges in the condenser current indicate discharges due to imperfect voltage neutralization at the beginning of the short-circuit period.

The oscillograms shown do not represent operation as satisfactory as is obtainable at larger currents; they were selected as best typical of Figs. 2 and 3. A ninth harmonic of voltage, probably due to the reactions in the auxiliary machines, appears on heavier loads which modifies the forms of $I_t$ and $I_c$ considerably but produces no change in the quality of the transits (see Fig. 12 for heavier loads).

## Automatic Adjustment of $E_r$ and $E_n$

In order to make a check on the perfection of the automatic adjustments of the harmonic voltages $E_r$ and $E_n$ with load changes, it was decided to cause a transient load change. Two values of field excitation for the d-c system machine were found, one resulting in nominal direct current inverting and the other giving the same current rectifying. By the throw of a switch the rectifier could suddenly be thrown from one operating condition into the other. Since the transient associated with field decay giving a change from inversion to rectification practically was complete within 2 seconds, it was selected for the oscillograms of Fig. 12. It will be noted that $E_n$ decreases with the a-c system voltage, $E_r$ passes through zero and reverses in phase at the cross-over point, $I_a$ undergoes similar changes, the direct current and the three-phase watts reverse at the same point. This performance seems promising since it was obtained by means of auxiliary apparatus not especially designed for the purpose. No arbitrary adjustments of any kind were possible during the passing of this transient and the commutation was perfectly black during the period.

### INVERTER WITHOUT A-C EXCITATION

The commutator operates without sparking when the a-c system is totally disconnected and, with the help of the transformers and condensers, generates polyphase voltages of non-sinusoidal wave form. Contrary to what was at first believed, the apparatus can supply not only power but also polyphase excitation to the a-c system as demonstrated by the following experiment.

The inverter was supplied with nominal d-c voltage. A balanced three-phase resistance load (5 amp nom.) was arranged to be thrown on suddenly. A highly reactive balanced three-phase load of 5 amp was similarly arranged. The transient of Fig. 13 occurred when the non-inductive load was disconnected and the inductive load thrown on. None but the automatic adjustments of $E_n$ and $E_r$ could occur during the period. The transits were satisfactory and the commutation absolutely sparkless. The excessive voltage amplitudes during the no-load period are due to the stored energy in the high d-c line reactance. A moderate reactance at this point will result in reasonable values of the a-c voltage.

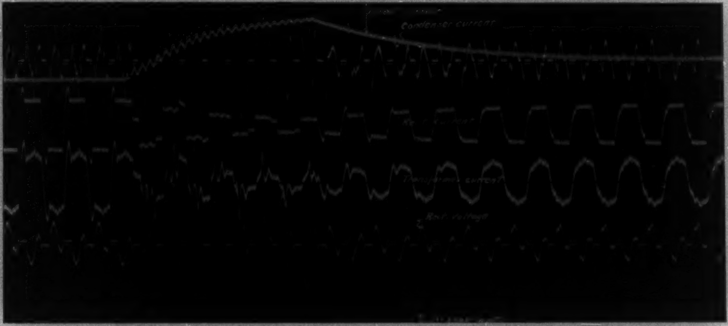

FIG. 13—INVERTER OPERATION WITHOUT A-C EXCITATION

Transient from three-phase resistance load to three-phase highly reactive load

The apparatus has been operated on currents up to 25 amp (the limit of receiving machine) without sparking and with observed transits of the same form as those shown in the oscillograms. The highest d-c voltage used on rectification and inversion was 1,500. At this voltage, the current passed was 2 amp (the limit of the receiving d-c machine). The commutation was again sparkless. The apparatus demonstrated its sturdiness in that considerable changes in $E_r$, $E_n$ or brush position could be made under load without causing sparking.

### SUMMARY

The following conclusions may be drawn as a result of this work:

1. A synchronously driven rectifier of the short-circuiting type can be made to be perfectly reversible so as to permit operation as an inverter.

2. Theoretically correct a-c voltage conditions to assure proper commutation and sparkless operation may be secured by the use of two odd harmonic voltage components ($E_n$ and $E_r$).

3. The two harmonic components $E_n$ and $E_r$ can be automatically varied so as to secure successful operation on transient load changes including that of d-c short circuit.

4. The apparatus designed for the above uses is capable of delivering both power and excitation to an unexcited polyphase system.

5. A rectifier-inverter of the kind described can take the place of moderate-voltage converting or frequency-changing equipment and promises to be of use in the solution of the problem of high-voltage d-c power transmission.

### LIMITATIONS

1. The rectifier-inverter described is a rotating machine.

2. The problems of rotor balance and of wear must find solution.

3. The practical voltage limits have not been determined.

4. When used in connection with high total a-c system reactance, a considerable kva capacity of auxiliary machinery and condensers is required.

### ACKNOWLEDGMENT

The author wishes to acknowledge the suggestions and encouragement given by the electrical engineering faculty of the Massachusetts Institute of Technology where this work was pursued as a doctor's thesis. He also expresses his appreciation of the important help of Professor N. S. Hibshman, of Lehigh University, in the conduct of the experimental work and the preparation

of the paper, and to Professor A. R. Miller for valuable assistance in taking and preparing oscillograms.

## Discussion

**N. S. Hibshman:** Since the author's remarks on the subject of the application of the rectifier have been confined to the field of high-voltage transmission where system reactances are necessarily high, and the use of a static condenser as an aid to commutation has therefore been assumed, it may be pertinent to add that the condenser is not essential to the operation of the rectifier, but is rather to be considered as a means of relieving the duty of the quadrature third-harmonic voltage to whatever extent the economics of the particular case may dictate.

The maximum value of the quadrature third harmonic, or commutating voltage, is given by equation (2) in the paper. Assuming several values of system reactances and for each plotting the commutating voltage ($E_r$) amplitude in per cent of fundamental amplitude as a function of capacitance the graphs of Fig. 1 result. It then appears that satisfactory commutation may be had with any combination of capacitance and $E_r$ within the limits shown. It will be seen that in a low-reactance system such as would be associated with a low-voltage power rectifier, the condenser has little effect and may be eliminated without material effect on the required percentage of $E_r$. However, according to equation (3), it appears that the condenser component of harmonic current has an important influence on the value of the neutralizing harmonic voltage and that the elimination of the condenser will call for considerable increase in the amplitude of the generated $E_n$.

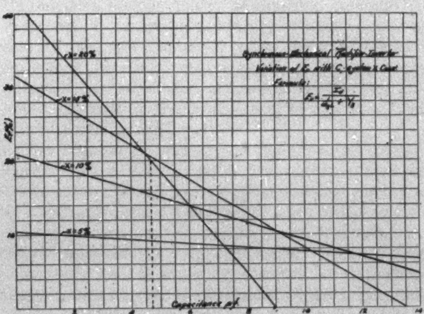

FIG. 1—COMMUTATING VOLTAGE, $E_r$, IN PER CENT OF FUNDAMENTAL PHASE VOLTAGE PLOTTED AGAINST CONDENSER CAPACITANCE FOR REPRESENTATIVE SYSTEM REACTANCES

The oscillograms in Fig. 2 were made while the rectifier operated without condensers, and show that the quality of commutation is unimpaired by the absence of the condenser when its function is supplanted by the proper increase in commutating and neutralizing voltages.

The oscillograms were made with the rectifier operating as part of a miniature three-phase system of 20 per cent reactance in which the nominal d-c load was 5 amperes. The experimental rectifier has delivered 25 amperes when operating on high reactance systems and as much as 75 amperes on low reactance systems. The latter current represents an average current density at the brush contacts of 200 amperes per square inch. At no time, however, has the capacity of the experimental rectifier been reached, the load limit having been set by the capacity of auxiliary equipment in all cases.

**H. E. Kent:** The oscillograms in the paper indicate the presence of considerable wave shape distortion on both the a-c and d-c side of the rectifier-inverter. This is of interest in its bearing on the coordination of power and communication systems from the standpoint of noise induction, since power system wave shape is an important factor in this problem.

In recent years there have been a number of cases of noise interference in telephone circuits where wave shape distortion caused by mercury arc rectifiers was involved. Experience has shown that in those situations involving wave shape distortion on the d-c load side of a rectifier selective devices such as resonant shunts offer a feasible method of reducing such distortion. However, where the a-c supply circuits to a rectifier are concerned in a case of interference, the problem is more difficult and no generally applicable solution has been found. The Joint Subcommittee on Development and Research of the N.E.L.A. and Bell System is actively working on this latter aspect of the wave shape distortion caused by mercury arc rectifiers.

In view of the difficulties which have been experienced in attempting to improve the wave shape of the a-c supply lines to rectifiers by the application of external equipment it would appear to be very desirable that consideration be given to wave shape during the development stage of these new types of rectifiers and inverters.

**J. J. Linebaugh:** Professor Seyfert has given an interesting analysis and description of a synchronous-mechanical rectifier-inverter, but it is evident that a great amount of work will be required to obtain a practical commercial unit even for fairly low voltages.

There are many difficult problems in the design of a mechanical rectifier commutator to take care of appreciable currents and the writer believes such a commutator is still to be developed. During the years 1924-27, the writer was actively connected with Mr. T. C. Lennox in an attempt to build such a commutator and, although after several trials a fairly successful commutator was produced, it still had serious limitations for large capacities.

It would be interesting to learn why standard graphite brushes were not used instead of the copper brushes with their short life and inclination to cut and wear the segments. The copper dust from such brushes is also very objectionable especially for high voltage commutators.

Did Professor Seyfert try to overload the sample commutator or raise the amperes to be commutated above 25 amperes?

**S. S. Seyfert:** Replying to the question of Mr. Linebaugh as to the highest currents and voltages that can be handled by this rectifier-inverter, the writer would recall Professor Hibshman's discussion; which stated that the largest direct current passed by the experimental apparatus was 75 amperes with an a-c system reactance of 5 per cent. This value was reached as the practical limit of the auxiliary machines' capacity for furnishing the harmonic voltage. The theoretical limit of current, apart from that imposed by the auxiliaries, is the brush contact area provided by the design. The voltage limit is determined by the arcover value or by the exactness of voltage neutralization that can be maintained.

Carbon brushes were at least temporarily abandoned for laminated copper because the lack of facilities prevented the securing of dynamic balance of the rotor. The metal brushes rode the rings perfectly in spite of considerable vibration. Under normal operation, no biting action at the segment tips was noted and the rotor was trued but once during the experiments, after a period of unusual abuse.

In response to Mr. Kent's suggestion that consideration be given to the harmonics in the a-c supply system, it may be said that, although the a-c wave form acting from line to neutral in the transformers is modified greatly by the insertion of the harmonics into the neutral connection, the voltage between lines still remains sinusoidal. In the connection shown by Fig. 5 of the paper, the 3rd harmonic components of current and multiples thereof such as the 9th, 15th, etc., must needs flow in the neutral connection to the generating source. This flow of the harmonics may be prevented or at least greatly reduced by locating the condensers $C_1$, $C_2$ and $C_3$ between lines and neutral immediately to the left of the harmonic generator $A_h$ without seriously impairing their effectiveness as an aid to commutation.

Although the apparatus was developed with the idea of applying it to the solution of the problem of high-voltage transmission, it would at present appear that the application attended with least practical difficulty would be that of rectification or inversion in connection with moderate voltage systems. When so applied, there should result a considerable reduction in capital investment and a large increase in efficiency since the estimated losses would be but slightly greater than the nominal losses in the transformers.

# Progress Report on Impulse Testing of Commercial Transformers[‡]

BY F. J. VOGEL[*]
Associate, A.I.E.E.

and

V. M. MONTSINGER[†]
Fellow, A.I.E.E.

***Synopsis.****—The transformer subcommittee of the A.I.E.E. electrical machinery committee presents herewith a progress report covering its work to date on the impulse voltage testing of commercial electric power transformers. A tentative test procedure has been agreed upon, although complete agreement has not yet been reached on all details. It is hoped that this report will stimulate among members of the Institute discussion that will be helpful to the committee in completing a formal test code during the coming year.*

AT THE A.I.E.E. winter convention in January 1932, the electrical machinery committee of the Institute assigned to the transformer subcommittee the task of determining the feasibility of impulse voltage tests on commercial transformers and of making recommendations for such tests, if possible. Agreement has been reached on a tentative test procedure, although complete agreement has not yet been reached on all details.

One of the first questions considered was the possibility of detecting impulse voltage failures. Transformers in service show the effects of insulation failure only by their inability to deliver power and by the formation of power arcs within the windings. For this reason, the combination of normal frequency excitation with impulse tests was carefully considered, since with this arrangement service conditions are duplicated and a transformer withstanding a test of this kind reasonably might be expected to stand up in service. Considerable experience with such a method already had been obtained when the subcommittee undertook this study, and the results of this experience appeared favorable; the subcommittee therefore devoted its efforts to the development of a practical test procedure along this line.

The purpose of making impulse tests on a transformer is to give a reasonable demonstration that the transformer has met the specification requirements as to impulse strength. The low frequency dielectric tests that have been used in the past cannot demonstrate this because the low frequency test voltage is of lower magnitude and is uniformly distributed throughout the winding, whereas the lightning voltage is generally of much higher magnitude and may depart radically from a uniform distribution. Impulse tests therefore will give a more adequate demonstration of the sufficiency of the insulation strength of transformers for service conditions.

## EQUIPMENT REQUIRED FOR TESTING

Impulse testing equipment (generator, discharge circuit, cathode ray oscillograph, and voltage divider) shall consist of only such parts and circuits as can be analyzed readily regarding the constants which have an appreciable effect upon the shape and amplitude of the voltage wave applied to the transformer under test. Such factors as the capacitance and inductance of the transformer under test, length of circuit from impulse generator to transformer, length of cable from divider to cathode ray oscillograph, length of main discharge circuit, as well as electromagnetic and electrostatic interference effects all must be taken into consideration. Testing technique and operation of the testing equipment should be that best suited for the purpose.

The equipment, in addition to that required for the producing and recording the waves, will consist generally of a source of power for exciting the transformer under test, means for synchronizing the impulse wave with the crest of the alternating voltage wave, a standard point gap, and means for limiting the power-follow across the gap. A technique of cathode ray oscillograph measurement should be developed for each test equipment so that the accuracy of the oscillograph and its potentiometer with respect to both time and voltage can be demonstrated.

The equipment should be located as closely together as possible. Nevertheless, it is necessary to provide sufficient space between all parts of the equipment so that there is no interference, and to provide for practical considerations. With this in mind, and to permit reasonable accuracy, it is recommended that the transformer terminals, coordinating or test gaps, and measuring equipment be within a range of less than 150 circuit feet.

## METHODS OF APPLYING TESTS

Constants of the surge generator should be adjusted so that the specified wave shape is obtained with the transformer connected. After the proper initial adjustments for the transformer under test are completed, changes in the test voltage can be made by varying the voltage applied to the surge generator, without requiring additional demonstration in regard to wave

*Presented at the A.I.E.E. Winter Convention, New York, N. Y., January 23-27, 1933.*

shape. Should the voltage applied to the transformer be changed by changing the constants of the circuit, it will be necessary, of course, to demonstrate the wave shape for the changed conditions.

The impulse wave should be applied with the transformer excited and with the wave synchronized at or within 30° of the crest of the excitation voltage. The two waves should be of opposite polarity at the time of synchronization, as this provides the severest test of the windings.

The test should be made on one terminal at a time. This simplifies test procedure, and generally will satisfy all requirements for a rigid test. Where series transformers for regulating purposes or other similar equipment require special protective devices, these should be in the circuit during the tests. During each test all bushings on windings not being tested will be either grounded or protected by appropriate means.

### TYPE OF WAVE TO BE APPLIED

The full wave will be satisfactory if it has a nominal front of from ½ to 2½ μsec, and a tail reaching half the crest voltage in from 40 to 50 μsec from the point on the front of the wave at which the voltage is 10 per cent of the crest voltage. The nominal front of the wave can be determined by measuring the time between points on the front at which the voltage is, respectively, 10 and 90 per cent of the crest value; this time divided by 0.8 will define the front of the wave. If there are oscillations on the front of the wave, the 10- and 90-per cent points should be determined from the average smooth wave front sketched in over the oscillations. The wave should be as smooth as possible because oscillations have the effect of increasing the stress on the winding under test. The wave shape should be recorded by the cathode ray oscillograph.

### TESTS TO BE APPLIED

In all tests the transformer tank will be grounded directly and test gaps, where they are used, will be connected directly to the same ground. Each terminal of the transformer to be tested should be tested with waves of positive polarity having respectively:

1. A voltage not more than 10 per cent less than the minimum impulse voltage permitted by the specified test gap directly connected to ground.
2. A voltage just sufficient to flashover the specified test gap directly connected to ground.
3. A crest voltage at least 10 per cent greater than the minimum flashover voltage of the test gap directly connected to ground.
4. A voltage of sufficient magnitude to flashover the bushing.
5. A voltage as great as that specified in No. 3 or 4, but with means for maintaining the excitation voltage across all parts of the winding. The purpose of this requirement is to prevent short-circuiting the windings through the power follow over the gap or bushing immediately after the impulse, which would cause the dynamic voltage to collapse and thus prevent the detection of an internal failure.

It is recognized that these tests do not make any allowance for the effects of variations in humidity and relative air density, and may not provide tests of the desired severity. However, the transformer subcommittee is giving consideration to these matters.

The transformer bushing and test gap shall have a minimum flashover voltage at least 10 per cent greater than the minimum flashover voltage of the proposed standard A.I.E.E. coordination gaps.[1] To obtain this, test gaps as indicated in Table I will be used.

### THE DETECTION OF FAILURES

Because of the nature of impulse voltage failures, one of the most important matters is the detection of failure. There are a number of positive indications of insulation failure. Some of these are: noise within the transformer; presence of smoke; excessive current or drop in voltage in the excitation circuit; failure of the gap or bushing to flashover when actually a sufficient surge voltage is applied; presence of oscillations or other variations from the expected wave shape as indicated by cathode ray oscillograms. These are positive indications of failure and will satisfy all practical requirements.

TABLE I—TEST GAPS RECOMMENDED FOR IMPULSE TESTING OF TRANSFORMERS

| Circuit voltage class, Kv | Tentative standard coordination gap, In. | Test gaps, In. |
|---|---|---|
| 2.3- 4.3 Y | 2* | 2¼ |
| 4.6- 8.67 Y | 3* | 3³/⁸ |
| 6.9-13.8 or 15 Y or Δ | 4¼ | 4¾ |
| 23 | 6¼ | 7 |
| 34.5 | 9¼ | 10¼ |
| 46 | 12¼ | 13½ |
| 69 | 18¾ | 20½ |
| 92 | 25 | 27½ |
| 115 | 31½ | 34¾ |
| 138 | 38¼ | 42 |
| 161 | 44½ | 49 |
| 196 | 54½ | 60 |
| 230 | 64 | 70½ |

# Factors Influencing the Insulation Coordination of Transformers

BY F. J. VOGEL*

Associate, A.I.E.E.

## INTRODUCTION

IN the early days of the electrical industry, surges were relatively mysterious as to their origin, magnitude and behavior. The ordinary factory tests now required by the A.I.E.E. rules were the reflection of experience and judgment rather than the analysis which has been made possible in the last few years. From experience, it was found on the one hand that it was necessary to increase the insulation of some parts of the transformers far above the requirements of the A.I.E.E. rules (*i. e.*, turn and coil insulation, bushings) and, on the other hand, to limit the voltages transmitted to the transformer from the line, by the specification of line insulation and protective gaps.[1] In the meanwhile, progress has been made in the laboratory study of the surge characteristics of the insulators, gaps, and insulation structures commonly used in transformers.[2] This paper presents data from these insulation studies and shows the relationships between the present coordination standards and the strength of transformer insulation. The results of tests of insulation under oil are reported, the strength of the various voltage ratings of transformers estimated and these in turn compared to the flashover values of line insulation and gaps.

## SURGE STRENGTH OF INSULATIONS UNDER OIL

The heart of the insulation of a transformer, as determined by the present A.I.E.E. rules, is in the insulation between the high-voltage and low-voltage windings, commonly known to the designer as major insulation. It is desired to keep these insulation clearances as small as possible to obtain low reactance, low losses, and the greatest economy in materials. The conventional means of obtaining such a result is in the use of tubes and angle rings in the core type transformer, and in the use of sheets and angles interleaved in the shell type transformer. Such constructions are shown in Figs. 1 and 2. Accordingly, models using these constructions were made and given both 60-cycle and surge tests, for the purpose of obtaining data on the strength of major insulation.

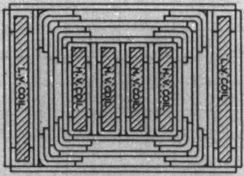

FIG. 1—VIEW OF SHELL TYPE TRANSFORMER INSULATION IN IRON OPENING

High-voltage and low-voltage coils are shown shaded

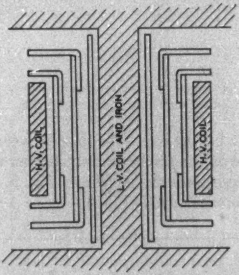

FIG. 2—VIEW OF CORE TYPE TRANSFORMER INSULATION MODEL

The low-voltage coil and iron are represented as one piece

It should clearly be understood that the results obtained apply only to the major insulation and do not represent the insulation strengths of complete transformers unless the insulation between turns and coils has been so made that even under the conditions of surge tests the major insulation is the weakest part of the entire structure.

The shell type models were first given 60-cycle tests to breakdown voltage. The results of these tests are as given in Table I. The procedure of testing was to hold the voltage 60 seconds, to allow 5 minutes rest and then to increase the voltage to the next step.

TABLE I—TESTS ON SHELL TYPE INSULATION MODELS
60 CYCLE—70 DEG C OIL

| Model | Voltage held 1 min—kv rms | Voltage at failure—kv rms |
|---|---|---|
| 15 | 280 | 290 |
| 16 | 300 | 310 |
| 17 | 290 | 300 |
| 18 | 270 | 280 |
| 20 | 260 | 270 |
|  | 280 | 290 |
| Average | 280 | 290 |

Similar models were tested to breakdown with positive surges at both Trafford and Sharon. The waves used were approximately 1½ μsec front and 40 μsec from the crest to half value. The results of these tests are plotted in Fig. 3. The comparison between these results and the 60-cycle tests (approx. impulse ratio) is shown in Fig. 4.

*Transformer Engineering Department, Sharon Works, Westinghouse Electric & Mfg. Co.

1. For references see bibliography.

*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

The core type models were likewise tested at 60 cycles to breakdown, with results as given in Table II.

TABLE II—TESTS ON CORE TYPE INSULATION MODELS 60 CYCLE—70 DEG C OIL

| Model | Voltage held 1 min—kv rms | Voltage at failure—kv rms |
|---|---|---|
| 3 | 300 | 310 |
| 4 | 270 | 280 |
| 7 | 300 | 310 |
| 8 | 320 | 330 |
| 9 | 280 | 290 |
| 10 | 310 | 320 |
| 11 | 300 | 310 |
| 12 | 320 | 330 |
| Average | 300 | 310 |

Surge tests on the core type models were made similarly to those on the shell type transformer models. The results of these tests are shown in Fig. 5, and the approximate impulse ratio in Fig. 6.

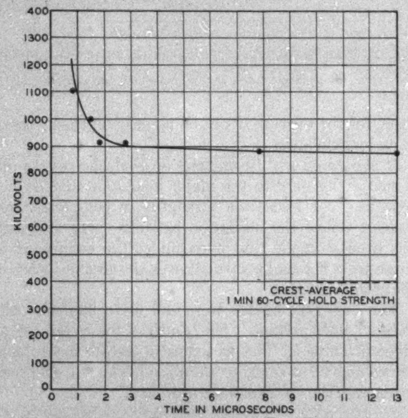

FIG. 3—TIME LAG CURVE OF SHELL TYPE TRANSFORMER INSULATION MODEL USING 1½-40 POSITIVE WAVE

It may be objected that these are not representative of all types of major insulation. These tests represent conditions where the dielectric field is formed between metal surfaces with square corners. The highest puncture voltages for a given distance have been obtained with flat sheets, in which case the formation of corona on the surface appears to result in a more uniform distribution of dielectric stress through the sheet. A comparison of the 60-cycle and surge strength for such conditions has been made. The barrier consisted of two ⅛-in. fullerboard sheets and two ⅜-in. oil ducts, as shown in Fig. 7. The extension of the barrier beyond the electrode was such as to produce puncture. The results of this test are given below:

| Max. 60-cycle hold strength 60 sec test | | Surge strength | | Impulse ratio |
|---|---|---|---|---|
| Rms | Crest | Voltage | Time lag | |
| 156 kv | 221 kv | 485 kv | 4.5 μsec | 2.2 |
| | | 450 kv | 5.5 μsec | 2.04 |

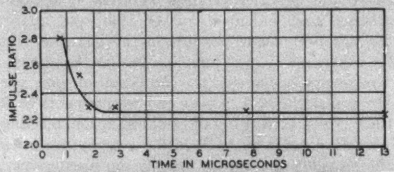

FIG. 4—IMPULSE RATIO CURVE OF SHELL TYPE TRANSFORMER INSULATION FOR 1½-40 POSITIVE WAVE

Indications in these tests were that the time lag curve was quite flat as even with increased voltage settings of the surge generator, no appreciable increase in breakdown voltage was obtained.

Similar tests with negative surges have been made. To accelerate the work, barriers similar to Fig. 8 were made, which simulate the conditions of interleaved insulation in the models. The average 60-cycle breakdown was found to be 345-kv rms or 490-kv crest.

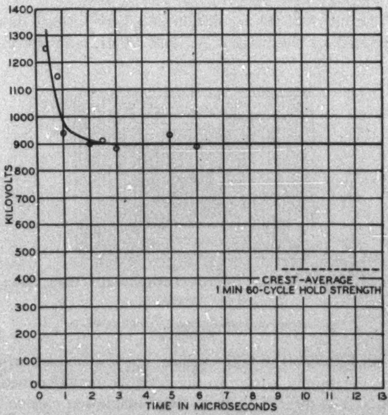

FIG. 5—TIME LAG CURVE OF CORE TYPE TRANSFORMER INSULATION MODEL USING 1½-40 POSITIVE WAVE

Positive time lag data are shown in Fig. 9, along with the results for the tests with negative waves. The average time lag curve of the major insulation of transformers, whether positive or negative, is therefore seen to be nearly the same and to be flat down to at least two or three microseconds.

To sum up these tests, it appears that the impulse ratio of transformer major insulation for time lags of the order of 2 microseconds or longer is approximately 2.2. These conclusions have been checked by tests of complete transformers and windings, where adequate winding strength, as in surge proof transformers,[3] was obtained.

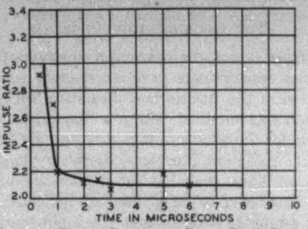

FIG. 6—IMPULSE RATIO CURVE OF CORE TYPE TRANSFORMER INSULATION FOR 1½-40 POSITIVE WAVE

## COMPARISON OF SURGE STRENGTHS OF INSULATORS, GAPS, BUSHINGS AND TRANSFORMER MAJOR INSULATION

In recent articles,[2] the strength of insulators and gaps has been published, and it is now possible to compare these against transformer insulation strength. This is best done by the use of time-lag curves. Accordingly typical time-lag curves of the 66-, 132- and 220-kv classes are shown in Fig. 10. In these curves, the standard conditions of air density and humidity of 25 deg C, 760 mm barometer and 6.5 grains of water vapor per cu ft of air are assumed. Further, in estimating the surge strength of the transformer insulation, the factor of 2.2 times the standard test voltage has been used which assumes the same factor of safety in the surge test for the major insulation as for the 60-cycle test. Since the factor of safety on test is unknown for different manufacturers, this makes the assumption that test or guarantee is not within closer limits for surge strength than for the 60-cycle breakdown strength.

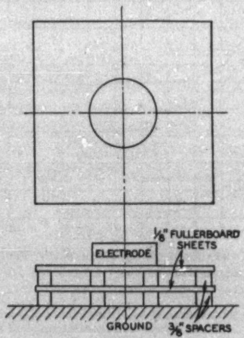

FIG. 7—ARRANGEMENT OF ELECTRODE AND INSULATION TO DETERMINE MAXIMUM PUNCTURE STRENGTH OF FULLERBOARD AND OIL DUCTS

Total thickness of fullerboard and ducts is 1 inch

For purposes of analysis, it is suggested that the 230-kv insulation class be chosen. From the curves, Fig. 10, the possible relationship between the service coordination gap, test gap or bushing, the previous standard of line insulation and the transformer insulation can be seen.

First, curve *C* shows the position of the line insulation with regard to the transformer insulation. This is of interest for two reasons. One is that it shows that coordination at short time lags might not be obtained with the recommended line insulation if the transformer were built just to meet the prescribed A.I.E.E. high-voltage winding tests. Another fact disclosed is that if the bushing is in excess of the line insulation, the margin between the bushing and transformer insulation may be greatly reduced.

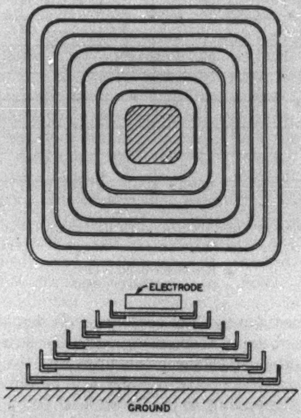

FIG. 8—ARRANGEMENT OF ELECTRODES AND INTERLEAVED INSULATION FOR CHECKING RESULTS OF MODEL TESTS AND FOR THE INVESTIGATION OF NEGATIVE SURGES

Next curve *A* shows the position of the coordinating gap relative to the transformer insulation. It is readily seen that ample margin will be obtained except at extremely short time lags, and since the time lag curve for transformer insulation also turns up, a margin is obtained.

The position of a proposed minimum bushing level is next shown as curve *B*. Several advantages of this level can be cited. First, it is desirable to keep this level as low as possible to provide a maximum margin between the insulation strength and the bushing flashover. Second, a sufficient margin above the coordinating gap is necessary to prevent bushing flashover in service. A minimum margin of 10 per cent probably satisfies both requirements to the best advantage. It should be particularly observed that protection to the extent of the coordinating gap cannot be obtained with the bushing, but the greatest degree possible will be obtained by keeping the bushing to the lowest level.

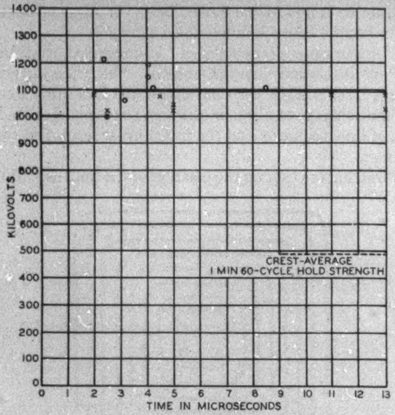

FIG. 9—SURGE VOLTAGE STRENGTH OF INTERLEAVED BARRIER FOR BOTH POSITIVE AND NEGATIVE WAVES

*x* Results for positive waves
*o* Results for negative waves

It is to be noted that the above relationships are for standard air density, humidity and positive waves. From inspection of the time lag curves, it will be seen that the shorter time lags are the critical ones. From inspection of the data furnished by Mr. F. D. Fielder, on density and humidity effects on gaps,[2] it is not believed that density or humidity conditions above the standard will appreciably affect the voltages at these short time lags. They will, however, be of importance for the longer time lags but here the margin of strength for the insulation is much greater.

Tests have been made with negative waves and they indicate little increase in voltage for short time lags compared to positive waves. There is however some increase in the voltage for long time lags due to change in polarity. Complete data of the effect of humidity on negative waves is not yet available. Nevertheless it is important that the effect of negative waves be considered. One reason for this is the fact that the highest lightning surges on lines have generally been found to be negative.[4]

An estimated curve of the relationships existing between the standard point gap and insulation for negative waves is shown on curve 11, for the 230-kv class. This is of interest in indicating still further the desirability of keeping the bushing characteristics at the lowest level.

## THE COORDINATION PROBLEM

Originally it was the opinion of engineers generally that since transformers gave satisfactory service, coordination of the transformer insulation with the line insulation was obtained. Surge voltage data were not available for the effects of humidity and air density on the line insulators, nor was there any appreciable amount of data available for insulations under oil. Service experience is not a thorough indicator of surge voltage strength, because first the number of strokes close enough to the station to result in the highest stresses possible is small, and second, even if close, the electrical constants of the transformer and substation may greatly modify and reduce them. It is of interest, therefore, (see Fig. 10) to note that with major insulation designed just to meet the requirements of the standard A.I.E.E. tests, coordination with the line insulators would have been obtained in the higher voltage classes except at very short time lags. The margin

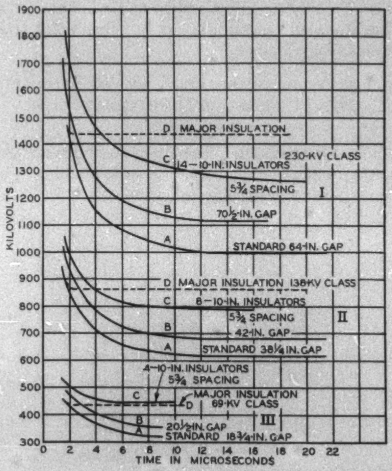

FIG. 10—COMPARISON OF POSITIVE WAVE TIME LAG CURVES FOR TRANSFORMER INSULATION WITH LINE INSULATION AND STANDARD GAPS

Group I is for 230-kv class, Group II is for 138-kv class and Group III is for 69-kv class. *A* for all classes is the present standard coordinating gap time-lag curve for the voltage class. *B* is the curve for the proposed gap for testing purposes and is a proposed bushing level. *C* is the curve for the line insulation formerly proposed for coordinating purposes. *D* is the minimum possible curve for the major insulation level based on the standard A.I.E.E. tests from the high-voltage winding to the low-voltage winding and ground of coordination diminishes in the lower voltage classes, disappearing entirely at the 69-kv class.

The point gaps more recently proposed show a logical agreement between the major insulation strength of transformers and the requirements dictated by experience. For example, the gap spacings used are in agreement with experience in furnishing comparatively longer spacings for the lower voltages, and are also logical in furnishing a simple relationship between the full wave values and the voltage class of the insulation as shown in Fig. 12.

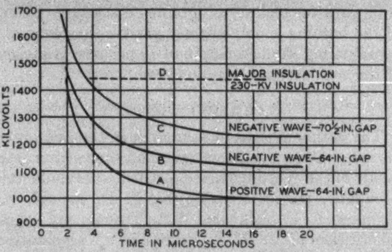

Fig. 11—Comparison of Positive and Negative Wave Time Lag Curves for Gaps and Transformer Insulation for the 230-Kv Class

*A* is the time-lag curve for a positive wave, the standard 64-in. gap and corrected to standard atmospheric conditions. *B* is the time-lag curve for a negative wave and the standard 64-in. gap, not corrected to standard atmospheric conditions. *C* is the curve for a negative wave for a 70½-in. gap proposed as a test standard and bushing level. *D* is the transformer insulation level

The surge strength of the major insulation and the gaps approach each other closest at a time lag of about 2 microseconds, due to the difference in the shape of their time lag characteristics. In determining whether major insulation is properly coordinated, it is necessary therefore to examine the conditions at the 2-microsecond point and make certain that at this point a margin does exist. Hence it is of interest to make an investigation of this sort in the several voltage classes to determine if major insulation designed to meet the requirements of the standard A.I.E.E. tests would be coordinated with the standard gaps at the 2-microsecond point. The results of such an investigation are presented in Table III.

In this table an effort has been made to arrive at logical values for the surge voltage requirements of the major insulation for the different voltage classes. It shows that in voltage classes 34.5 kv and above, the requirement that coordination be obtained at the 2-microsecond point will determine the necessary surge voltage strength of the major insulation, and that these surge voltage strengths so obtained, when translated into corresponding 60-cycle tests, give values almost exactly in agreement with the present standard A.I.E.E. tests. In the lower voltage classes, however, this requirement would dictate surge voltage strengths less than would be required to meet the surge tests proposed by the Transformer Subcommittee, so that in these lower voltage classes the proposed surge tests would dictate the necessary surge voltage strengths of the major insulation. These strengths translated into corresponding 60-cycle tests indicate that the present A.I.E.E. tests must appreciably be increased in these lower voltage classes.

Particular attention should be given to Fig. 10, in that the characteristics of the various time lag curves vary so radically. In the coordination work so far accomplished, characteristics such as obtained with the point gap or insulator strings only have been considered. The possibility of coordinating with a gap having impulse characteristics of similar shape to transformer insulation is an alternative. Such a gap might be a sphere gap. With the use of such a gap, a uniform factor of safety would be possible between transformer major insulation and the gap, instead of the variation now experienced between short and long time lags. An example of the results to be expected from such an arrangement is indicated as follows:

TABLE III

| Voltage class | Coordinating gap | Full wave (1½—40) standard gap | 2 microsecond strength standard gap | Major insulation transf. surge strength requirements (B) | 60-cycle (C) test req'd by surge strength | Present 60-cycle test |
|---|---|---|---|---|---|---|
| 2,300— 4,330 | 2 (A) | 55 | 55 | 1.21 × 55 = 67 | 21.6 (D) | 10 |
| 4,600— 8,670 | 3 (A) | 75 | 80 | 1.21 × 75 = 91 | 29.2 (D) | 18.4 |
| 6,900—13,800 | 4¼ | 95 | 105 | 1.21 × 95 = 115 | 37 (D) | 28.6 |
| 23,000 | 6¼ | 125 | 150 | 1.21 × 125 = 151 | 48.5 | 47 |
| 34,500 | 9¼ | 175 | 215 | 2 μsec value = 215 | 69.3 | 70 |
| 46,000 | 12¼ | 225 | 285 | 285 | 91.5 | 93 |
| 69,000 | 18¾ | 325 | 425 | 425 | 137 | 139 |
| 92,000 | 25 | 425 | 570 | 570 | 183 | 185 |
| 115,000 | 31½ | 525 | 715 | 715 | 230 | 231 |
| 138,000 | 38¼ | 625 | 860 | 860 | 276 | 277 |
| 161,000 | 44½ | 725 | 1,000 | 1,000 | 322 | 323 |
| 230,000 | 64 | 1,020 | 1,440 | 1,440 | 462 | 461 |

(A) Proposed values.

(B) Major insulation requirements up to the 23-kv class are determined to meet surge tests 10 per cent above the flashover of a gap which is 10 per cent higher than the standard gap. In the higher voltage classes the major insulation strength is determined by the requirement that coordination must be obtained at a time lag of 2 microseconds.

(C) Surge strengths divided by $\sqrt{2}$ and by 2.2.

(D) Manufacturers have long recognized the necessity for higher insulation strengths of these transformers, and it has generally been built in.

Any gap used should be protected by lightning arresters, to obtain continuity of service. The discharge voltage of an autovalve arrester for 230-kv service is in the neighborhood of 850 kv. The coordinating gap used might then be set to furnish some desired margin, and in turn a further margin taken for the transformer insulation above the gap. The total of these margins might then be 20 per cent, or 1,020 kv. This impulse strength would correspond to a 60-cycle test voltage of 328 kv. Since the present required test voltage is 461 kv, the possibility of reduction in surge strength requirements by such coordinating means is shown. It should be pointed out that in this case coordination with present designs of bushings would be impossible.

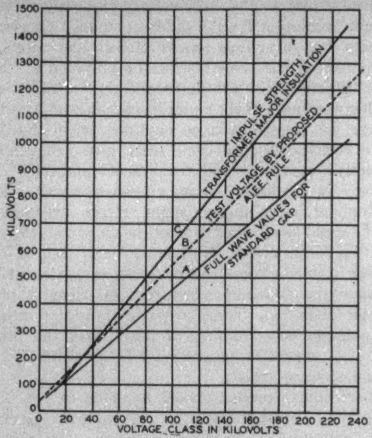

FIG. 12—CURVES SHOWING IMPULSE VOLTAGE REQUIREMENTS OF TRANSFORMERS

*A* gives the full wave values for the standard gaps and for the 1½-40 positive wave and is represented by the equation kv = 30 + 4.22 *L* where kv is the full wave value and *L* is the line voltage in kv. *B* gives the maximum test values according to the proposal of using a gap 10 per cent in excess of the standard gaps, and testing at 10 per cent in excess of the full wave value. The equation for *B* is kv = 36 + 5.1 *L*. *C* represents the voltages to give about 2 microseconds time lag for the standard gaps, and also represents the critical limit for coordination. Where *C* is in excess of *B* it represents the design limit for transformers. The equation for *C* is kv = 6.25 *L*

## SUMMARY

The following conclusions have been reached:

1. The time lag characteristics of major insulation are practically the same for both positive and negative waves.
2. The impulse ratio of major insulation is practically 2.2.
3. The present standard A.I.E.E. tests for the 34.5-kv class and above provide coordination with the proposed coordinating gaps.
4. A.I.E.E. tests below 34.5-kv class are too low and should be increased.
5. Greatest security is obtained if the surge flashover of the bushing is only slightly greater than that of the coordinating gap. A margin of 10 per cent is suggested as the most desirable bushing level.

## ACKNOWLEDGMENT

The author desires to acknowledge the assistance of his associates in the laboratories and engineering departments of the Westinghouse Electric and Manufacturing Company, particularly Messrs. F. D. Fielder, E. J. Grimmer, C. F. Alsing and W. L. Teague, and the helpful criticism of Mr. H. V. Putman in the preparation of this paper.

# Coordination of Insulation

BY V. M. MONTSINGER* Fellow, A.I.E.E.
W. L. LLOYD, JR.* Member, A.I.E.E.
and J. E. CLEM† Member, A.I.E.E.

***Synopsis.**—The general scheme of coordination is discussed. Average circuit insulation used in 1930 is shown. The relation that switching surges and arcing ground overvoltages bear on coordination is discussed giving the number and magnitude of such waves found in service. Levels of insulation in and around the station for outdoor and indoor apparatus are suggested.*

*It is pointed out why a point gap offers the most reliable method of establishing the level for impulse testing of transformers. Also, reasons are given why bushings as made at present should not be used as the sole level for impulse testing.*

*It is shown that on account of the similarity of the volt-time curves for insulations and sphere gaps for short impulse waves, the use of a sphere gap in parallel with a rod gap will give an added protection against direct strokes on or near the apparatus terminals. Also, various proposed schemes are shown to give protection to the transformer and against outages for both fast and slow waves.*

*For potential and current transformers having voltage ratings differing from standard it is suggested that the coordination gaps be selected from the curve of gaps vs. rated circuit voltages.*

*It is shown how an air gap of standardized construction can be used to advantage in expressing the impulse flashover of insulators and bushings. Curves are given showing the gap spacings that are the equivalent in flashover to suspension and pedestal insulators for the ½/5, 1/10 and 1½/40 positive and negative waves. A proposed method to reduce the negative flashover of bushings is given.*

*The effect of the shape of electrodes on the 60-cycle flashover of gaps is discussed and data given. Positive and negative impulse flashover values are given for coordination gaps, standard suspension and pedestal insulators. Also, the effect of humidity on the flashover of gaps and insulators is shown for the ½/5, 1/10 and 1½/40 waves.*

* * * * *

## GENERAL

THE general principle of coordination of system insulation is the selection of insulation in proportion to the anticipated overvoltages. Particularly, the lightning overvoltages are considered as limited by a coordination gap, which thereby establishes the insulation level at which coordination is made. The use of the gap alone does not result in maximum operating reliability. Operating reliability at any system voltage can be increased by liberal use of protective schemes, by increasing the insulation safety factor in relation to the coordination gap, or by increasing the spacing of the coordination gap and establishing coordination at a higher level. On the other hand, proper use of voltage limiting and protective schemes will permit coordination at a lower gap level and reduce costs without sacrificing operating reliability.

In Table I is shown the average circuit insulation for circuits 44-kv and up on lines which were in existence in 1930. It was at first proposed that the adjacent line insulation be used to limit the voltage which might be applied to a station. This was not entirely satisfactory, since the adjustment could be made only in steps of one unit. Also, if the place of flashover can be localized at a point it is more convenient for maintenance of the gap and for the prevention of flashover by lightning arresters. Accordingly, the use of a gap was finally proposed and adopted. This gap is called the "coordination gap" and is used to set a maximum limit to the applied stresses and not as a protective device.

The overvoltages which may appear on a system may be divided into two classes; switching surges and arcing ground voltages in the first class, and lightning impulses in the second class. The overvoltages due to switching and arcing grounds are usually of such a nature that the 60-cycle flashover voltages of the gap and station insulation should be considered in analyzing the possibility of flashover. This conclusion is based on a study[1] of surge voltage recorder records over a period of several years. In this study the wave front of the switching surges was determined. The study of the data indicated that the lower voltage surges had wave fronts relatively slow, while the higher voltage surges had steeper and steeper wave fronts.

TABLE I—AVERAGE CIRCUIT INSULATION

| Nominal circuit voltage | No. units[1] Actual average | No. units[1] Proposed[2] | Coordination gap inches |
|---|---|---|---|
| 13.2 | | | 4 |
| 22 | | | 6¼ |
| 33 | | | 9¼ |
| 44 | 3 | | 12¼ |
| 66 | 5 | 4 | 18¾ |
| 88 | 6 | 6 | 25 |
| 110 | 7 | 7 | 31½ |
| 132 | 10[3] | 8 | 38¾ |
| 154 | 10 | 10 | 44½ |
| 187 | 10 | 12 | 54½ |
| 220 | 13[4] | 14 | 64 |

[1] No. units refers to standard 5¾ in. by 10 in. suspension line insulators.

[2] Originally proposed as reference insulation level.

[3] These are mostly 4¾ in. by 10 in. units—approximately equivalent to 8 standard 5¾ in. by 10 in. units.

[4] Mostly Pacific Coast Region.

In Table II there is shown a tabulation of switching surges covering a period of four years. These data are plotted in Fig. 1. Out of a total of 854 measured switching surges only 4 were above 5 times normal; of these 4, 2 were 5.2 times and 2 were 5.5 times line-to-neutral voltage. It does not seem necessary nor even reasonable to select insulation on the basis of the maximum switching surge overvoltage. There is considerable evidence that if the 60-cycle flashover voltage is more than 4 times normal, there will be very little probability of flashover from switching surges. As a corollary it can

| Total | 854 | 486 | 185 | 41 | 4[4] |

[1] Includes line to Conowingo.

[2] Miscellaneous properties over the country.

[3] Recorders in 1930 were set so that they did not record any surges less than 1.6 times normal.

[4] Of the 4 above 5 times normal, 2 were 5.5 times.

be stated that there is no need for coordinating the 60-cycle flashover voltage of station apparatus, providing no insulation used has a 60-cycle flashover less than 4 times the normal line-to-neutral voltage of the system.

The overvoltages due to arcing grounds[2] are of the same order of magnitude as the switching surges on an ungrounded system and of lower magnitude on a grounded system. The wave fronts correspond to those of switching surges, so that the insulation requirement should be the same for both switching surges and arcing ground overvoltages. If insulation is satisfactory from consideration of switching surges, it should also be satisfactory in regard to arcing ground overvoltages.

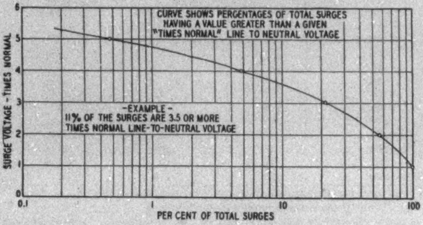

FIG. 1—SWITCHING SURGES—1927-28-29-30

Fundamentally, the lightning overvoltages on the line are independent of and are considerably in excess of any overvoltages set up by the system voltage, and therefore it is only necessary to coordinate with the gap on the basis of lightning overvoltages. The use of a coordination gap at the station to limit the lightning stresses establishes a definite level for design purposes. The line insulation then becomes entirely independent of the station insulation and the line may be designed to suit local conditions. The station insulation can always be referred to the coordination gap for the design level and uniform standards can be set up.

Lightning investigations[3] during the past few years have clearly brought out the fact that lightning impulses occur over a wide range of wave shapes. On this account there is no typical lightning wave. Since the flashover voltage of insulations is affected by the shape of the applied impulse, it is necessary to set up a wave shape, or wave shapes, for coordination purposes. The two most generally used waves have been the ½/5 and 1½/40 microsecond waves. Generally speaking, if coordination is obtained on short waves proper coordination is obtained for longer waves.

Polarity also affects the flashover, the negative wave usually requiring the higher voltage. It is obvious that coordination should be attained in respect to both polarities. It is highly probable that if practical coordination is attained on the positive wave, it will automatically be attained for the negative wave, since the effect of polarity is generally less on gaps than on other apparatus.

It has been proposed from time to time that there be a number of steps or levels of insulation within a station. This is not logical since nothing is gained by increasing the flashover of any part of the station equipment as far as external insulation is concerned. Therefore, the maximum reliability for a given investment is obtained by making the insulation in a station area uniform.

While the obvious place for the coordination gap to limit the lightning overvoltage applied to the station, is at the junction of the line and station, transformers frequently provide a reflection point and accordingly it becomes necessary to locate a coordination gap closely adjacent to the transformer, not more than 100 circuit feet distant for 69 kv and above, and not more than 50 circuit feet distant below 69 kv. This assumes that direct strokes are prevented from reaching the station circuits. Overhead ground wires properly placed provide the best method of accomplishing this.

Thus far the gap has been considered as a device for setting a maximum to the voltage which may be applied to the station apparatus. This gap, however, cannot function unless the applied voltage is greater than the flashover voltage of the gap and, therefore, it offers no relief from repeated application of voltages up to its flashover. When the gap does function an outage results. Accordingly, the gap is not a protective device in the true sense of the word.

The best way to reduce the voltage applied to station apparatus below the limiting value allowed by the coordination gap is through the use of a lightning arrester. The lightning arrester can be designed to reduce all voltages other than direct strokes which are more than a relatively small percentage above the maximum normal frequency voltage and thereby offers protection from overvoltages above this value. Therefore, it increases the operating safety factor between the tested impulse strength of the station apparatus and equipment and the applied impulse voltage. Experience indicates that with modern arresters, gap flashovers are of rare occurrence. The use of the arrester thus prevents interruptions to service by preventing gap flashover, and at the same time absence of gap flashover demonstrates the ability of the arrester to perform its functions satisfactorily.

Since altitude affects the impulse flashover of gaps and other station apparatus similarly the coordination gap should be increased as the air density decreases at the higher altitudes.

### Distribution Voltages

When circuit voltages below 15 kv are considered the problem of coordination becomes very involved. In this region, in addition to transformers, there are generators, motors, and synchronous condensers, as well as switching devices. Here, past practise has not developed insulation strength as great as that in outdoor transformers and station equipment such as bus supports and disconnecting devices. Before the final solution of this problem can be reached, a great deal of further work must be done. Tentatively, equipment in this range may be divided into two classes, "outdoor" and "indoor." The proposed coordination gaps for 13,800, 8,700, and 4,500 volts are 4 in., 3 in. and 2 in. respectively for the "outdoor" classification and might be 3 in., 2¼ in. and 1½ in. respectively for the "indoor" classification.

### Cables

The situation in regard to cables is much more encouraging. While the cable itself is more or less of a protective device and reduces the lightning overvoltages coming in from the line, the insulation strength of the cable and of the pothead should be in line with other station equipment whenever cables are used. When the cable joins two overhead lines the coordination gap should be used to set the maximum voltage and lightning arrester protection[4] should be used if the cable is short enough to need it.

### Transformers

The coordination scheme in respect to transformers is that the transformer bushing be coordinated with the coordination gap and the windings be made stronger than the bushing. The real purpose back of this is a desire to make sure that the transformer bushing can flash over without failure occurring in the windings. Since transformer coordination is to be made on the basis of the bushing, it is obvious that this requires the standardization of the impulse flashover of bushings in reference to the coordination gap for each specific voltage class. Bushings as at present used by the manufacturers have different flashover values and so do not fulfill this requirement. Consequently, the present designs of bushings are not a comparative basis for transformer coordination. It then becomes necessary to set up standards for the impulse strength of bushings. It is proposed that the standard flashover of bushings be 15 per cent higher than the flashover of the coordination gap on impulse.

Since the bushing is to be used as a level for making impulse tests on windings the impulse flashover of all bushings must be standardized. Furthermore, means should be provided for adjusting the arcing distance to get the same kilovolt value under all humidity and air density conditions since the dielectric strength of oil-immersed windings is not affected by changes in the atmosphere. This can be done on General Electric bushings and probably on other types by attaching a short adjustable gap to the base or center clamp which gap will also serve to reduce the negative flashover values.

Again, on account of differences in atmospheric conditions manufacturers are often asked to furnish for the same rated circuit voltage bushings whose creepage distance and arcing lengths are larger than the standard. It is true that oversized bushings can and have been provided in certain cases with gaps to reduce the impulse flashover. Some operators, however, object to gaps on bushings, preferring to depend upon an outside gap to take the flashovers. To require that the winding be stronger than the flashover of these special bushings is unsound economically because to follow this practise would require that the impulse strength of windings be made stronger merely on account of poor atmospheric conditions.

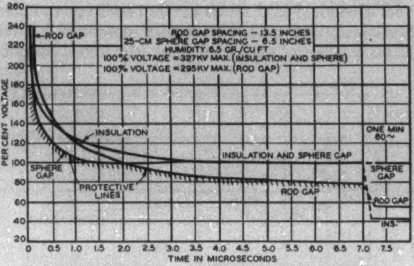

Fig. 2—Relative Impulse Strengths (Volt-Time Curves) of an Insulation Barrier, a Rod Gap and a Sphere Gap—1.5/40 Positive Wave

The sphere gap curve plotted above is not intended to represent the curve of a laboratory sphere gap. It is intended to approximate the curve of a sphere gap as might be affected by dirt and other adverse conditions in practical installation. It is thus a pessimistic curve

The impulse level for which transformers (both windings and bushings) are to be insulated and tested, should therefore be established by something that will give the same results when used by all manufacturers. A standardized air gap is the best device available at the present time.

### Coordination of Transformers with Coordination Gaps

*Waves Other Than Direct Strokes.* The proposed coordination gaps will perform their intended function when subjected to any kind of waves that may come in over the line as the result of induced strokes or of direct strokes on the line out some distance from the station. The rod form of coordination gap has been selected because of its convenience and because it is not readily affected by dirt, corrosion, rain, etc.

*Direct Strokes.* This paper would not be complete, however, if it did not include the results of research and suggestions for protection for very steep front waves that may occur in the rare cases of direct strokes at or very near the terminals of the apparatus. The difference between direct stroke waves and indirect stroke waves is that the former are likely to have very steep fronts whereas the latter have more sloping fronts.

A large number of tests has shown that the margin of safety between a given insulation and a rod gap decreases as the applied wave front decreases or approaches the effect of a direct stroke. Accordingly, if it is desirable to keep a given margin of safety in practise for direct strokes at the apparatus terminals, the rod gap spacings must be less than those applied for the usual conditions.

It is quite important, therefore, to compare the relative dielectric strengths of insulation and coordination gaps for waves with fronts down to a small fraction of a microsecond. Fig. 2 shows curves based upon impulse breakdown tests made on a barrier (described in Table III) composed of solid insulations with intervening oil ducts representing major insulation from high-voltage to low-voltage windings and ground. Solid insulations (pressboard, herkolite, varnished cambric immersed in oil, etc.) have practically the same volt-time characteristics. The rod gap structure used corresponded to that which has been recommended for coordination.

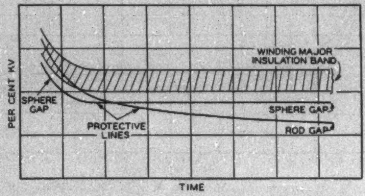

FIG. 3—CHARACTERISTIC VOLT-TIME CURVES FOR TRANSFORMER WINDINGS, A ROD GAP AND A SPHERE GAP

It will be noted that the insulation curve is practically flat down to three microseconds while the gap curve has a sloping characteristic to approximately 0.7 μsec, and for shorter periods rises at a very fast rate. It can be seen, therefore, that with rod gap protection, the factor of safety rapidly diminishes with the steepness of the wave front, particularly for periods at 1 μsec and less. Whether or not these curves cross on a transformer depends upon the insulation margin in the apparatus. However, it was considered of interest to plot these characteristics for a barrier of insulation and gaps. Noting the figure, it is seen that for this particular barrier of insulation the rod gap ceases to give any margin of protection at about 0.8 μsec where the margin is 10 per cent at 2 microseconds. The 10 per cent margin is the same as the proposed difference between the test gap and coordination gap. On this same curve sphere gap characteristics are also shown. In this case the sphere is set to give equal protection as the rod gap at 2 μsec and it will also be noted that the spheres give complete protection down to very short periods of time. Eventually, for the longer periods of time, the insulation curve departs from the sphere gap curve because it must come down to the 60-cycle one minute strength which is in the order of one-half or less than the 1 or 2 μsec gap strength,—the sphere gap curve, of course, remaining flat down to the 60-cycle time. These curves show that for short periods of time, within the direct stroke period, a sphere gap forms the ideal coordination gap.

The one-minute 60-cycle crest breakdown strength of the barrier was 42.5 per cent of the impulse strength, thus giving an impulse ratio of 2.35. This value checks the impulse ratio obtained on sample coil stacks.

In making the impulse tests a 1½/40 positive wave was used. Obviously the breakdown points beyond 1.5 microseconds occurred on the tail of the wave while those for periods of time shorter than 1.5 μsec occurred on the front of the wave (obtained by applying overvoltages of varying magnitudes). In the case where the 0.2 μsec time is shown no series resistance was used in the generator circuit in order to get as steep a wave front as possible.

Fig. 3 shows a sphere gap and a coordination gap applied to transformer insulation. In this particular figure the transformer insulation is represented as a band rather than a line, since it is intended to cover a wide voltage range of different makes and types of transformers.

It is quite evident from the foregoing that if the setting of a rod gap gives reasonable margin for transformer protection for the usual waves coming from the transmission line, it will not give a reasonable margin for direct strokes at or near the terminals.

The most direct way of showing the relative impulse strengths of insulation, a rod and a sphere gap is to show the equivalent gap spacings that represent the breakdown point of the insulation for various overvoltages applied to the insulation. The tests were made by applying a given voltage or overvoltage to the gap and insulation in parallel and increasing the gap setting at 5 minute intervals until the insulation failed. The results are given in Table III.

On the other hand, the rod gap is the ideal coordination gap for the longer waves because of its sloping curve where it follows fairly closely the volt-time characteristics of bushings and other types of station insulators.

A gap having the short time characteristics of spheres and the long time characteristics of rods would be the ideal coordination gap where no other direct stroke protection is provided. Such a gap is available and consists of a sphere gap in parallel with a rod gap. The characteristics of such a gap have been known and it was recommended several years ago.[5]

TABLE III—GAP SPACINGS EQUIVALENT TO THE PUNCTURE OF INSULATION BARRIER*

| ½/5 Positive wave | | | 1½/40 Positive wave | | |
|---|---|---|---|---|---|
| Applied voltage in % of min. full wave to cause breakdown | Gap spacings in inches | | Applied voltage in % of min. full wave to cause breakdown | Gap spacings in inches | |
| | 25 cm spheres | Rod gap | | 25 cm spheres | Rod gap |
| 100 | 5.7 | 14.4 | 100 | 6.5 | 20.5 |
| 125 (approx.) | 5.9 | 12.5 | 135 (approx.) | 7.8 | 17.0 |

Note: Humidity of air during rod gap test 1.25 grains per cu ft.

*Composed of 1/8 in. oil, 1/16 in. P. B., 1/8 in. oil, 1/16 in. P. B., 1/8 in. oil between a 4 in. dia. electrode and a large flat plate. In all cases direct puncture of the barrier took place. All values average of at least three tests.

†With zero series resistance in generator circuit.

‡General average of widely varying values.

What are the requirements that such a gap must meet? In the first place, the spheres must be set wide enough so that they will not flash over during switching surges. A safe minimum level for this would seem to be 4 times line-to-neutral voltage as shown elsewhere in this paper. Unfortunately, the 60-cycle wet flashover of spheres horizontally mounted is approximately 50 per cent of the dry flashover. Therefore, an uncovered sphere gap would have to be set for a dry flashover of 8 times line-to-neutral voltage. On this basis the sphere gap impulse flashover would be equal approximately to the ½/5 full wave flashover of the proposed standard coordination gap.

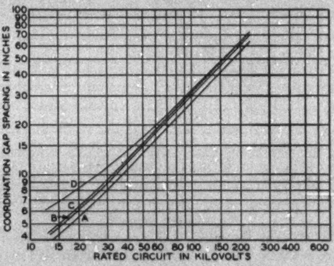

FIG. 4—PROPOSED COORDINATION AND TEST GAP SPACINGS

Also proposed bushing levels expressed in terms of gap spacings that give 50-50 flashover when tested in parallel with bushings with positive impulse waves.

*A*—Proposed coordination gaps
*B*—Proposed test gaps
*C*—Proposed standard bushings
*D*—Proposed special bushings for power transformers

On the other hand, if the spheres are kept dry, by some sort of a covering, so far as switching surges are concerned, a much greater degree of protection to the apparatus could be obtained. That is, the sphere gap could be set for 4 times normal voltage or 50 per cent of that allowable under wet sphere conditions. This low setting, however, would cause an undue number of outages from lightning waves. Somewhere in this wide band is the proper setting to give the maximum benefit compatible with the permissible outages. Just where this point is would no doubt have to be determined by experience in the field, and may vary depending upon local conditions; that is, the frequency of lightning and station design and other protection used. The ideal gap then would be composed of a rod gap in parallel with a covered sphere gap.

There are also possibilities of making a coordination gap composed of two or more gaps in series arranged with shunt capacitance or resistance, etc., so that the time-lag curve is improved as compared with that for a simple rod gap, and which has approximately the same 60-cycle wet and dry flashover values.

Another possible method of obtaining a gap as fast as a single sphere gap (but in less space and possibly at a reduced cost) would be to use a number of smaller spheres in series mounted on or attached to a stack of pedestal insulators with the size and spacing properly adjusted with the voltage gradient along the insulator stack.

The approximate minimum size of spheres for a single gap that would be required for the various circuit voltages is given in Table IV.

TABLE IV

| Rated circuit kv | Diameter of spheres | |
|---|---|---|
| | Cm | Inches |
| 13.8 | 6.25 | 2.47 |
| 23.0 | 12.5 | 4.9 |
| 34.5 | 15.0 | 5.9 |
| 46.0 | 20.0 | 7.85 |
| 69.0 | 30.0 | 11.8 |
| 115.0 | 50.0 | 19.7 |
| 138.0 | 63.5 | 25.0 |
| 161.0 | 75.0 | 29.6 |
| 230.0 | 100.0 | 39.4 |

## APPLICATION OF COMBINATION COORDINATION GAP

The combination gap would be needed only where it is not practical nor economical to provide other adequate forms of direct stroke protection such as overhead ground wires, etc. Very few, if any, modern high voltage stations would really need this gap as the simple rod gap would fulfill the requirements. The combination gap might be used as an added protection to a very important station where other direct stroke protection is provided.

## METHODS TO PROVIDE PROTECTION TO APPARATUS AND AGAINST OUTAGES

In addition to the combination gap another theoretically possible method of protecting the apparatus against strokes would be to provide means for sloping the wave front, thus causing the rod gap to flashover at a lower voltage. It should be kept in mind that slanting the wave front alone (kilovolts remaining the same) does not add any protection to the insulation. In fact, the breakdown voltage of insulation increases for very steep fronts (see Fig. 2). But the advantage of sloping the front comes in due to the fact that the rod gap on account of its volt-time characteristic prevents, by flashing over, the application of excessive voltage to the insulation.

While most schemes suggested for slanting wave fronts are impractical, capacitance seems to be the most promising means. Such a capacitance might be an intervening cable or specially designed capacitor.

The possible combinations for protection to apparatus and against outages for both direct strokes and traveling waves are summarized in Table V.

TABLE V—SHOWING VARIOUS SCHEMES OF PROTECTION AGAINST TRAVELING WAVES AND DIRECT STROKES

| Kind of protection | | | Type of wave for which protection is afforded | |
|---|---|---|---|---|
| Rod gap | Sphere gap | Other protection | (a) To transformer | (b) Against outages |
| Yes | No | None | Traveling wave | None |
| Yes | Yes | None | Traveling wave and direct stroke | None |
| Yes | No | L.A.[1] | Traveling wave | Traveling wave and direct stroke† |
| Yes | Yes | L.A | Traveling wave and direct stroke | Traveling wave and direct stroke† |
| Yes | No | C[2] | Traveling wave and direct stroke | None |
| Yes* | No | L.A. & C | Traveling wave and direct stroke | Traveling wave and direct stroke† |

*Would not be expected to arc when the arrester is operating properly.

†Provided the voltage allowed by the lightning arrester is kept below the flashover of the coordination gap.

[1] Lightning arrester.

[2] Capacitor (to slant the wave front to allow rod gap to take the flashover).

## Coordination of Potential and Current Transformers

The fact that some instrument transformers and other apparatus have voltage ratings (below 13.8 kv) differing from those shown in Table I somewhat complicates the problem of coordination. For example:—2.5 kv, 5.0 kv and 7.5 kv are voltage ratings often used for potential transformers. Rather than attempt to standardize coordination gap spacings for all voltage ratings it is recommended in cases where the voltage rating does not conform to the standard, that the coordination gaps be taken from a curve based on gap spacing *vs.* circuit voltage values given in Table I.

## Transformer Bushing Levels

As pointed out before, the impulse flashover of bushings is subject to some change by slight modification in the design without affecting the 60-cycle flashover values.

Fig. 4 gives the flashover of the proposed standard line of bushings and special bushings for power transformers in terms of equivalent gap spacings. For comparative purposes the coordination and test gap curves are given.

It will be noted that the gap used for making impulse tests (test gap) on transformers is 10 per cent above the coordination gap, and that the proposed standard bushing curve is 15 per cent above the coordination gap throughout. Also, it will be noted that the proposed bushing curve for power transformers is above the curve for standard bushings in the lower voltage range, being as high as 35 per cent above in the 13.8-kv class. The flashover voltage of bushings should be standardized and the bushings should be adjusted to equal the standard.

## Use of Point Gap in Coordination Work

The ideal method of measuring the impulse flashover of gaps, insulators, bushings, etc., would be to use something that has exactly the same flashover characteristics; *i.e.*, has the same humidity and air density, etc., corrections and maintains the same relationship for various waves. If such a device were available and if standard impulse curves were established for this device, when the flashover is desired for a string of special insulators, etc., it would only be necessary to test the insulators in parallel with the device and obtain a balanced condition; that is, obtain 50-50 flashover. This would eliminate the necessity of making corrections for the very troublesome factors such as humidity, air density and would also eliminate any error due to not having the impulse wave exactly of the correct shape. After all, what the operator is interested in most are the "relative flashover values" of the different apparatus. This would give it in the most direct method.

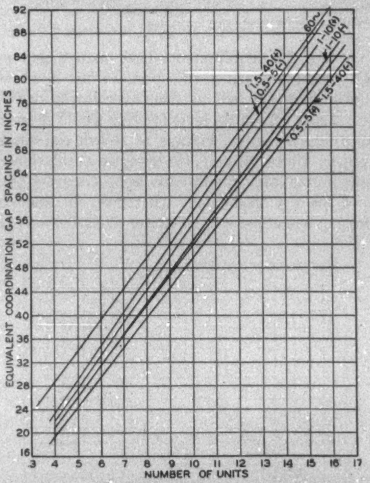

Fig. 5—Curves Showing Gap Spacings that Give 50-50 Flashover when Tested in Parallel with Standard 10-Inch Suspension Insulators, Spaced 5¾ Inches Apart

If the impulse kv values were desired they could be taken from the standard impulse curve for the device.

The coordination gap is not quite the ideal device because its relative or equivalent spacing changes slightly when tested in parallel with suspension and pedestal insulators for various lengths of waves. But considered from the standpoint of humidity and other corrections the gap is nearly ideal because practically the same corrections apply to it as to all other apparatus. The gap method offers a satisfactory means of expressing relative impulse strengths until the kilovolt values can be agreed upon.

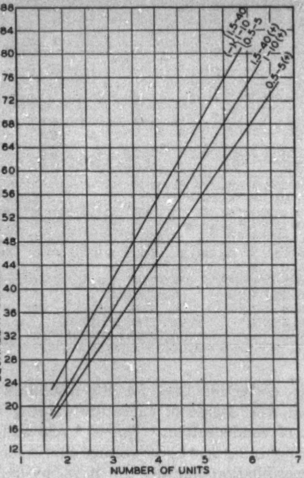

Fig. 6—Curves Showing Gap Spacings that Give 50-50 Flashover when Tested in Parallel with Locke No. 7785 Pedestal Insulators

Figs. 5 and 6 give the equivalent gap spacings (*i.e.*, the spacings that give 50-50 flashover when tested in parallel) for 10 in. suspension insulators and Locke No. 7785 pedestal insulators when tested with the ½/5, 1/10 and 1½/40 positive and negative waves. From these curves we see that the equivalent gaps for 8 suspension insulators are 42 in. and 46 in. for the ½/5 and 1½/40 positive waves respectively. The equivalent gaps for 4 Locke No. 7785 pedestal insulators are 44.5 in. and 49 in. for the ½/5 and 1½/40 positive waves respectively. If for practical purposes the average gap spacings were used, the error would be ± 5 per cent depending upon the wave being considered. This variation, in fact, is no greater and in some cases less than the difference in kilovolt obtained now by the different manufacturers' laboratories. For negative waves for pedestal insulators the equivalent gap values shown on the curve should be used since these are considerably greater than the values for the positive waves. They are the same for all three waves.

It should be pointed out, however, that equivalent gaps for other insulating parts having entirely different time lag characteristics can not be taken directly from standard full wave or minimum flashover curves obtained separately. In such a case it is necessary that the curves for the longer time lag be replaced by curves based upon sufficient overvoltage to make the time lags equal.

The advantages of using a standardized gap for determining and expressing the impulse flashover of other apparatus are as follows:

1. It enables an operator to obtain comparable data from the various manufacturers and thus simplifies the problem of coordination until such a time when the various laboratories can iron out their differences in kilovolt values.

2. It automatically makes correction for humidity and air density; also for slight variations in the wave shape and other factors which affect similarly both the gap and the apparatus under test.

The Pittsfield Laboratory has found that this method of measuring impulse flashover is very convenient and quite practical.

## Sparkover Data

The effect of humidity upon the lightning sparkover voltage of the proposed coordination gap for the 0.5/5, the 1.0/10 and 1.5/40 waves of positive polarity is shown in Fig. 7. This gap consists of square-ended square rods mounted as indicated in Fig. 8.

Similar data for various length strings of standard duty 10 in. by 5¾ in. cemented, cap and pin type, suspension insulators are shown in Fig. 9. From these figures it may be noted that the lightning sparkover voltage of the coordination gap and suspension insulator string increases as the humidity is increased. This is similar to the effect of humidity upon the 60-cycle sparkover voltage of insulators and gaps as previously noted.[6] The effect varies somewhat with the wave-shape. The voltage corrections for the three commonly used light-

ning waves and for 60 cycles are approximately as follows:

| | |
|---|---|
| 0.5/5 wave | 1¼% per grain per cu ft |
| 1.0/10 wave | 1½% per grain per cu ft |
| 1.5/40 wave | 2⅓% per grain per cu ft |
| 60 cycles | 3.0 % per grain per cu ft |

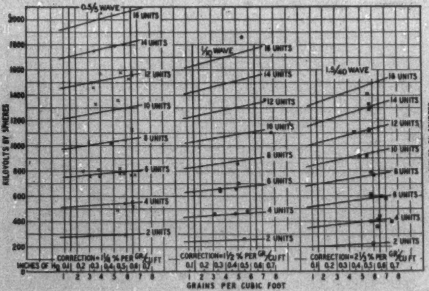

Fig. 9—Effect of Humidity on the Sparkover of Standard 10-Inch Suspension Insulators Spaced 5¾ Inches Apart

Positive polarity impulse waves

The corrections appear to continue as nearly straight lines up to at least 16 grains per cubic foot and to be very nearly the same for both insulators and coordination gaps, if precautions are taken to prevent condensation on the porcelain surfaces of the insulators at the higher humidities. Unless these precautions are taken curved humidity correction lines for the insulators may be measured, the degree of curvature varying with the amount of condensation. The 60 cycle and positive polarity lightning sparkover voltage curves for the proposed coordination gap and the 10 in. by 5¾ in. suspension insulator at an absolute humidity of 6.5 grains per cubic foot (14.87 grams per cubic meter) are shown, respectively, in Figs. 10 and 11.* This absolute humidity corresponds to a vapor pressure of 0.6085 inches (15.45 mm) of mercury and a relative humidity of 65

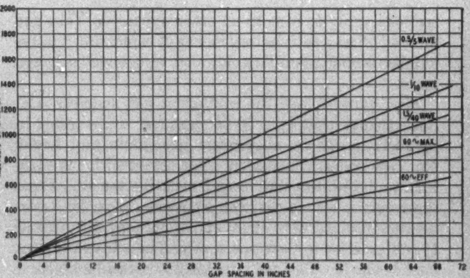

Fig. 10—Sparkover of Rod Gaps

5/8-inch square rods mounted as shown in Fig. 8. Humidity 6.5 grains/cu ft. Positive polarity impulse waves per cent at 77 deg F (25 deg C) and a barometric pressure of 30.0 inches (76.2 cm) of mercury.

---

*Measured points can not be given on these two figures since these curves are derived curves plotted from the data given in the two preceding figures for which the measured points are plotted.

In the A.I.E.E. Standards 41, dated March, 1930, on "Insulator Tests" it is stated that "flashover voltage shall be determined at or corrected to a standard humidity corresponding to a vapor pressure of 0.6085 in. (15.45 mm) of mercury. This is equivalent to a relative humidity of 65 per cent at 77 deg F (25 deg C) and a barometric pressure of 30.0 in. (76.2 cm) of mercury." Since it has been shown[6] that the flashover voltage varies with the absolute humidity rather than with the relative humidity, it is felt that reference to the relative humidity should be omitted. Also, since grains per cubic foot or grams per cubic meter is believed to be a term which is in more general use and one which conveys a somewhat greater meaning to the average engineer than does the term vapor pressure in inches or millimeters of mercury, it is suggested that the Institute Standards be changed to express absolute humidity in terms of grains per cubic foot (grams per cubic meter).

Positive polarity impulse waves

Fig. 12 presents the positive polarity lightning sparkover voltage curves for a heavy duty pedestal insulator commonly used for high voltage bus insulation in outdoor stations. The curves are plotted for an absolute humidity of 6.5 grains per cubic foot.

The negative polarity sparkover voltage curves of the coordination gap at a humidity of 6.5 grains per cubic foot are given in Fig. 13. While the negative data are not as extensive as the positive data, the negative short wave sparkover voltage of the coordination gap appears to be approximately the same as the positive short wave sparkover voltage, whereas the negative long wave sparkover voltage is appreciably higher than the positive long wave sparkover voltage.

The negative polarity sparkover voltage curves for various length strings of 10 in. by 5¾ in. suspension insulators at a humidity of 6.5 grains per cubic foot are given in Fig. 14. In contrast with the results obtained on the coordination gap, the negative short wave sparkover voltage of the insulator string is higher than the positive short wave sparkover voltage, whereas the negative long

TABLE VI—COORDINATION GAP—1.5/40 WAVE

| | Negative polarity | | Positive polarity | |
|---|---|---|---|---|
| Setting | Dry | Wet | Dry | Wet |
| 12 in. | 265 | 285 | 241 | 245 |
| 18 in. | 425 | 415 | 332 | 335 |
| 24 in. | 535 | 515 | 425 | 400 |

Suspension Insulators—1.5/40 Wave

| | Negative polarity | | Positive polarity | |
|---|---|---|---|---|
| No. of disks | Dry | Wet | Dry | Wet |
| 2 | 225 | 200 | 225 | 205 |
| 4 | 410 | 390 | 410 | 415 |
| 6 | 595 | 550 | 595 | 565 |

Disks are standard duty 10 in. by 5¾ in. cap and pin type units.

Artificial rain 0.2 in. per min. at 45 deg. Resistance = 15,000 ohms per cubic centimeter.

Temperature of water approximately 60 deg F (15 deg C).

Dry sparkover values corrected to unity air density and 6.5 grains per cubic foot (14.87 grams per cubic meter) absolute humidity.

wave sparkover voltage appears to be approximately the same as the positive long wave sparkover voltage.

The negative polarity lightning sparkover curves for station-bus pedestal insulators at 6.5 grains per cubic foot are given in Fig. 15. The negative short wave sparkover voltage appears to be approximately 20 per cent higher than the positive short wave sparkover voltage. The negative long wave sparkover voltage appears to be approximately 30 per cent higher than the positive long wave sparkover voltage.

Table VI gives some recent data on the effect of rain upon the lightning sparkover voltage of the coordination gap and the suspension insulator. The results are in agreement with the earlier tests.[6] The effect of rain varies from zero to 10 per cent with the long wave while with the short wave the effect is practically negligible.

TABLE VII—60-CYCLE DRY FLASHOVER KV EFFECTIVE (APPROXIMATE)

| | | 5/8 in. square rod | | 5/8 in. round rod |
|---|---|---|---|---|
| Gap inches | Needles | Square ends | Horns | Square ends |
| 2 | 35 | 40 | 55 | 55 |
| 4 | 55 | 60 | 100 | 90 |
| 8 | 90 | 100 | 180 | 150 |
| 12 | 120 | 125 | 215 | 195 |
| 16 | 155 | 160 | 240 | 220 |
| 24 | 220 | 230 | 280 | 255 |

That rain should have so little effect upon the lightning sparkover of gaps and insulators is not surprising when it is considered that the dielectric strength of water for impulse voltages is from 2 to 14 times the dielectric strength of air.[7]

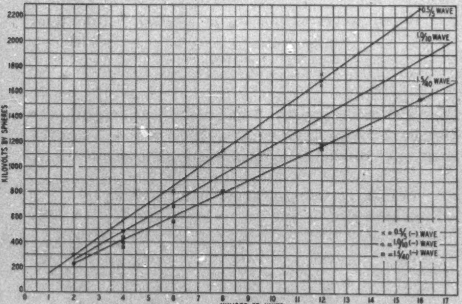

Fig. 14—Sparkover of Standard 10-Inch Suspension Insulators, Spaced 5¾ Inches Apart

Humidity 6.5 grains/cu ft
Negative polarity impulse waves

Table VII gives the 60-cycle dry flashover values of gaps having electrodes of different shapes.

The majority of the sparkover data presented in this paper was obtained in the High Voltage Engineering Laboratory in Pittsfield, Mass. Certain check tests, however, were conducted in the General Engineering Laboratory in Schenectady. Although the equipment, method of procedure and general technique followed in the two laboratories are quite different, the results checked within a few per cent. In both laboratories, the voltage is determined directly by means of the sphere-gap, as recommended by the A.I.E.E. Standards 41.

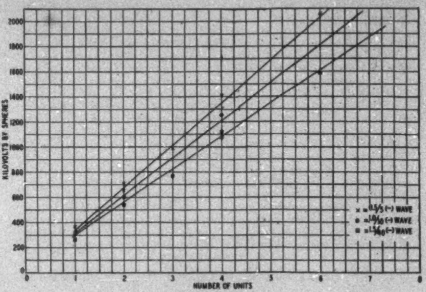

Fig. 15—Sparkover of Locke No. 7785 Pedestal Insulators

Humidity 6.5 grains/cu ft
Negative polarity impulse waves

It is also possible to measure the test voltage by means of oscillograph deflection if a voltage divider is used which reduces the test voltage to that applied to the oscillograph without introducing or eliminating superimposed oscillations on the indicated wave. By developing an accurate divider, this method of voltage measurement has also been employed in the Schenectady laboratory and in Pittsfield. Such measurements were depended upon however, only after it was determined that the voltage indicated by the oscillograph checked with the voltage indicated by the sphere gap for both the 0.5/5 and the 1.5/40 waves. Very accurate adjustment of the voltage divider is necessary to obtain this. A companion paper entitled *Laboratory Measurement of Impulse Voltages* by C. M. Foust and J. C. Dowell describes in detail the precautions necessary and gives the methods and general technique used in the two laboratories, the equipment employed to obtain an accurate measurement of the test voltage wave-shape and oscillograms of the waves used in these tests.

## Discussion

For discussion of this paper see page 440.

# Impulse Voltage Testing

BY C. F. HARDING[1] and C. S. SPRAGUE[2]
Fellow, A.I.E.E. Associate, A.I.E.E.

IN a recent paper before the Institute,[3] the authors presented the results of tests of a standard 2,300-4,000 to 115/230-volt distribution system upon which both induced and direct-stroke surge potentials were impressed as the result of the sudden charging of a thoroughly insulated cloud supported over the line. These tests were carried out as the result of the cooperation of the Utilities Research Commission of Chicago.

The four conclusions reported in the previous paper which are of particular interest and therefore worthy of the further study described in this paper are as follows:

In existing transformer design the insulation of the secondary winding may be overstressed by steep wave front surges without excessive stress on the primary insulation; such stresses may be relieved by improvements in secondary insulation.

Interconnecting the primary lightning arrester ground to the grounded neutral of the secondary main greatly reduces the voltages at the transformer and imposes no extra hazard upon the consumer's wiring.

Using "direct strokes" from the surge generator, the interconnection is of great benefit with high arrester ground resistances. With any combination of secondary neutral and arrester ground resistances, the interconnection limits the transformer stress to the value determined by the arrester voltage, and should reduce materially the lightning failures on non-surge-proof types of transformers.

With usual city conditions, consisting of a multiplicity of low resistance grounds on the secondary neutral, and the further possibility in some instances of a lightning arrester ground of high resistance, it has been demonstrated herein that potentials at the transformer may be reduced greatly by the interconnection of the primary lightning arrester ground and the grounded neutral of the secondary main.

During the course of these tests, the insulation of several of the non-surge-proof transformers was punctured while operating temporarily without the interconnection but with lightning protection having a high resistance ground. There is no doubt but that these break-downs of insulation would have been avoided had the conditions of this experimental investigation permitted operation with the interconnection at all times. Thus it is believed that a further protective method has been demonstrated for the thousands of the older types of distribution transformers now in service which, of course, must be retained in use for many years.

It was soon evident, however, that certain changes in the design and construction of these transformers would cause them to be practically surge proof. Transformers of various manufacturers' designs were tested subsequently, in the high potential surge laboratory. They withstood all of the exposures when provided with lightning arresters or equivalent internal protection. However, in the event of transformer installation without such lightning arrester protection or, in case of the failure of such protective devices to operate, the surge flashover of bushings and the insulation puncture values of the different types of transformers differ widely and provide undetermined factors of safety. Herein lies the line of demarcation, at the present time, between the various types of distribution transformers of the so-called surge-proof design and construction. Shall the prospective purchaser be content to depend upon either external or internal protective devices or shall he insist upon certain specified factors of safety for the bushing flashover and the insulation puncture values above the protective gap flashover value?

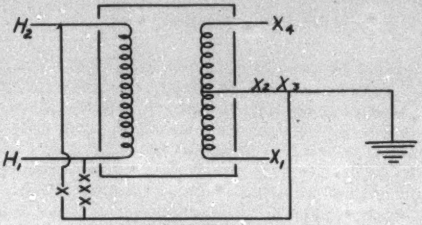

FIG. 1—CIRCUIT DIAGRAM FOR SURGE TESTS WITH EXTERNAL ARRESTERS

XXX = phase arrester
X = neutral arrester
Surge applied at $H_1$

## SURGE TESTS ON DISTRIBUTION TRANSFORMERS

The first tests consisted of impressing surges upon each transformer between primary phase lead $H_1$ and secondary neutral $X_2$, $X_3$, as indicated in Figs. 1 and 2. In these tests the case was ungrounded and the primary phase and neutral arresters were connected between the respective primary terminals and the grounded secondary neutral. It will be seen that this connection is equivalent to employing, in service, the interconnection of the secondary neutral and the primary lightning arrester ground.

As shown in the oscillogram of Fig. 3 the applied test wave had a peak value of 182 kv with the voltage increasing at an average rate of 50 kv per microsecond on the major part of the wave front. This wave was adopted by the committee of the Utilities Research Commission in charge of the project as being more representative of the wave which was more liable to reach the average distribution transformer than the steeper waves. Also, since the transformers were to be tested with arrester protection, this wave more nearly approximates the specifications for lightning arrester testing.

With arrester protection as described above the following readings of Table I and oscillograms Figs. 4 to 6 were taken of the voltages on the transformer.

Note: Arresters connected to secondary neutral when gaps $a$ and $b$ are not supplied

The oscillogram of Fig. 5 indicates the potential between the primary neutral and the secondary neutral of transformers Nos. 1 and 4 with the primary neutral arrester connected but evidently not operating. Another exactly similar oscillogram, but without the neutral arrester connection, indicated by its similarity to Fig. 5 that the neutral arrester had not operated in the former test. Fig. 6 illustrates how the potential of the ungrounded transformer case floats close to the potential of the secondary neutral. For one of the transformers with internal protection, with the primary arrester discharging into the case, Fig. 7 shows that the potential of the case floats close to the secondary neutral until the primary arrester breaks down, at which time the potential between the case and the secondary neutral rises to the break-down value of the coordinating gap between case and ground. Fig. 8 shows the arrester current for the external arrester used in these tests. A maximum of 1,670 amperes was obtained in approximately 8 microseconds. Essentially the same current was obtained with the internal gaps.

From the data of Table I, it will be noted that the external lightning arrester connected between the primary phase and the secondary neutral limits the voltage across the transformer to about 19 kv. In the case of the transformer No. 6 with inclosed arresters the maximum voltage was 53.8 kv. While this illustrates the beneficial effect of the interconnection, it is obvious that the transformer insulation was not subjected to a very severe test.

The voltages measured between the primary phase lead and the case, and between the case and the secondary neutral indicate that the ungrounded case assumes a potential close to that of the secondary winding. With transformer No. 6, however, the inclosed arresters discharge into the case and raise the potential between the case and the secondary to that determined by the breakdown of the case-to-ground, or the case-to-secondary-neutral gap, depending upon which gap was allowed to spark over in the tests. The surge breakdown of the case-to-ground gap was found to be 22.8 kv, that of the case-to-neutral gap was found to be 31.4 kv. For the transformer No. 6 the reading from the primary phase to the case gives the maximum arrester potential, in this instance 35.6 kv.

TABLE I—SURGE TESTS ON DISTRIBUTION TRANSFORMERS WITH ARRESTER PROTECTION

| | |
|---|---|

‡Path of flashover, inside case, phase lead to case 1-3/16 in., case to sec. lead 1-1/8 in.

§Path of flashover, primary phase lead to case, outside over bushing, 1 in., core bolt to secondary jumper, inside ⅛ in.

Voltages between the primary neutral and the secondary neutral were in some cases not sufficient to operate the 300-volt primary neutral arrester. Transformers Nos. 2 and 3 showed, with the primary neutral arrester removed, a voltage between the primary neutral and the secondary neutral somewhat higher than that between the primary phase and the secondary neutral. This seems to indicate that the primary windings of these transformers had broken down between turns or layers. The reconnection of the neutral arrester reduced the voltage on the primary neutral to about 8 kv indicating that this value was the surge breakdown of these arresters. The oscillograms of Fig. 9A and B illustrate the potentials between the primary neutral and the secondary neutral with and without the use of a primary neutral arrester connected as in Fig. 1. It may be noted here that transformers Nos. 2 and 3 were the same ones which indicated breakdown under direct stroke tests on the experimental distribution line. It was also noted in the laboratory surge tests on these two transformers, that when measuring the voltage between the primary phase and the case, a heavy discharge was obtained across the measuring gap, indicating the probable breakdown between the case and the grounded secondary.

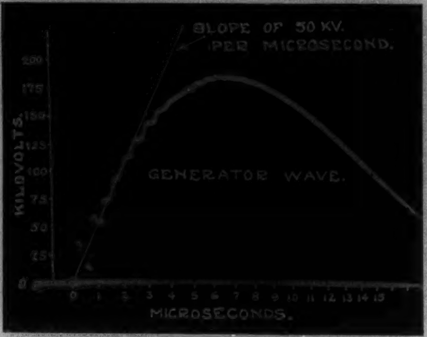

Fig. 3—Generator Wave

It was not considered feasible to energize the transformers when tested on the line. However, in tests where the insulation between turns or layers may be punctured, the transformer may be energized as a means of detecting this type of breakdown which might not be apparent otherwise.

Two of the older transformers, Nos. 8 and 9, not of the surge proof type, were tested, and showed no evidence of damage with arrester protection. The arresters were removed and the voltage increased until bushing flashover occurred at approximately 85 kv as noted in the table.

In addition to the surge tests of the transformers with protection, four transformers were tested without protection up to the point of insulation failure. As before the surge was applied between the primary phase lead and the secondary neutral lead. For these tests without protection a ½-10 wave was used. The peak voltage of the wave was increased gradually until failure of the transformer insulation occurred. With this type of test the breakdown would naturally occur on the tail of the wave. Table II presents the data obtained on these transformers.

TABLE II

| Transformer | Surge kv* | Remarks |
|---|---|---|
| *A* | 125 | Flashed over from the primary lead to the case and to the secondary lead over the surface of the oil |
| *A* | 162 | Insulation punctured |
| *B* | 146 | Flashed over from the primary lead to the case and to the secondary lead over the surface of the oil |
| *B* | 162 | Insulation punctured |
| *C* | 146 | Insulation punctured |
| *D* | 103 | Insulation punctured |

*Peak value of ½-10 wave.

Table II indicates for these transformers a range of insulation breakdown values from 100 to 160 kv. In all cases the breakdown occurred in the insulation between primary and secondary winding and did not involve the core or case.

After the tests on the transformers with and without arrester protection had been completed, the leads were disconnected from the windings and the following bushing flashover tests were performed:

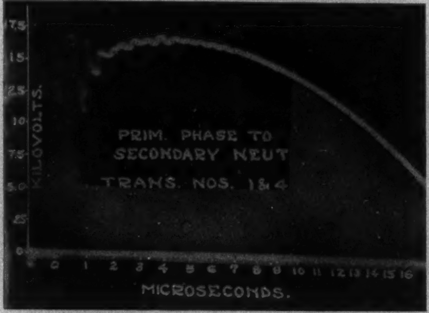

Fig. 4—Surge Potentials on Transformers With External Arrester Protection

Wet and dry flashover outside
Dry flashover inside

Each of the above flashover tests was made with 60-cycle voltage, with a 50 kv per $\mu$sec front surge, and with a 150 kv per $\mu$sec front surge.

Some of the transformers had their primary leads taped with several layers of varnished cambric. With this lead insulation the primary bushings withstood surges of 100-kv peak value. Since this value seemed to be of the order that might be expected of the winding insulation, the tests were not carried to the point of puncturing the lead insulation or flashing the primary bushings. Instead, a piece of No. 22 copper wire was coiled around the lead insulation as close as possible to the bushing and connected to the lead. This approximated the condition of completely deteriorated insulation on the leads of the transformers of this type. The values given in the following table apply to this condition.

With the transformers Nos. 1 and 4 the outside of the bushings was taped and painted in accordance with the standard specification of the Commonwealth Edison Company. For transformer No. 1 the bare metal was exposed inside the tank and there was no problem of lead insulation, while for transformer No. 4, extra leads were used in place of those furnished with the transformer, in order to avoid cutting the existing leads.

All flashover tests were conducted in accordance with the A.I.E.E. standard specifications for this type of testing.

The following Table III presents the flashover values of the transformer bushings.

TABLE III—60-CYCLE AND SURGE FLASHOVER OF TRANSFORMER BUSHINGS

60-Cycle and Surge Flashover of Transformer Bushings

| | |
|---|---|
| Barometer | 747-756 Mm |
| Temperature | 24-26° C |
| Humidity | 40-70% |
| Precipitation (For Wet Flashover Tests) | 0.192-0.205 In./Min |
| Water Resistivity (For Wet Flashover Tests) | 6,550 Ohms/Cu In. |

| | | Prim. phase or neutral bushing | | | Secondary bushing | | |
|---|---|---|---|---|---|---|---|
| | | Outside | | Inside | Outside | | Inside |
| Transformer No. | Type of voltage | Dry | Wet | Dry | Dry | Wet | Dry |
| 1 | 60 cycle (eff.) | 49.0 | 33.0 | 32.6 | 48.3 | 31.3 | 32.6 |
| | 50 kv/μs | 106.0 | 133.0 | 61.0 | 101.0 | 101.0 | 66.5 |
| | 150 kv/μs | 109.0 | 107.0 | 82.0 | 109.0 | 102.0 | 84.5 |
| 4 | 60 cycle (eff.) | 53.6 | 27.0 | 40.6 | 53.3 | 29.8 | 41.3 |
| | 50 kv/μs | 96.0 | 109.0 | 109.0 | 99.0 | 100.0 | 100.0 |
| | 150 kv/μs | 107.0 | 100.0 | 109.0 | 111.0 | 101.0 | 109.0 |
| 5 | 60 cycle (eff.) | 33.3 | 17.7 | 26.9 | 24.2 | 14.6 | 16.9 |
| | 50 kv/μs | 96.0 | 78.0 | 54.5 | 50.0 | 50.0 | 31.5 |
| | 150 kv/μs | 100.0 | 85.3 | 67.3 | 52.0 | 52.0 | 38.2 |
| 6 | 60 cycle (eff.) | 36.9 | 26.8 | 22.3 | 35.0 | 20.2 | 14.2 |
| | 50 kv/μs | 96.0 | 91.2 | 52.5 | 76.5 | 74.0 | 33.0 |
| | 150 kv/μs | 102.0 | 102.0 | 57.5 | 83.5 | 80.5 | 37.0 |

The data of Table III reveal, in general, that transformers Nos. 1 and 4 have somewhat higher bushing flashover values, especially inside the tank, than do Nos. 5 and 6. Transformer No. 4 shows higher flashover values inside the tank than does transformer No. 1. Of course, in making comparisons from the figures of the table it must be remembered that the flashover values of transformers Nos. 5 and 6 apply to the condition of completely deteriorated lead insulation.

A considerable variation is noted in the flashover values, outside the tank, of transformers Nos. 1 and 4. It seems evident that these are due to variations in the taping and painting of the bushings. Reasonable care was used in this operation but evidently uniform results were not obtained. It was interesting to note, during the tests, that in practically all cases the 60-cycle flashover punctured the tape, while the surge flashover went underneath the tape.

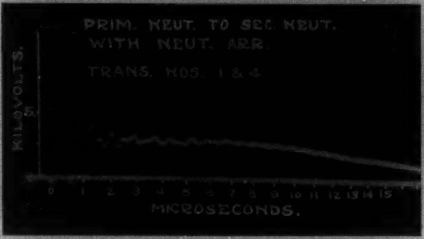

Fig. 5—Surge Potentials on Transformers With External Arrester Protection

With the 60-cycle bushing flashover inside the tank of transformer No. 4, the values in the table are the values of the first flashover. A large amount of carbonization occurred and unless the leads were removed and the bushings cleaned, the 60-cycle flashover value was observed to drop to 65 or 75 per cent of its initial value. This trouble was not noticeable to any extent on the surge flashover tests. It was observed that the inside bushing flashover of the transformer No. 4 did not puncture the lead insulation but followed the surface of the porcelain into the metal of the lead.

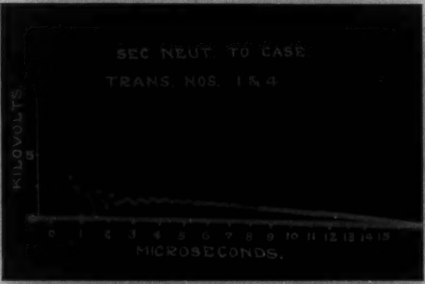

Fig. 6—Surge Potentials on Transformers With External Arrester Protection

The data of the table also indicate that the surge flashover under rain conditions is not materially different from that under dry conditions. In this respect it may be noted here that one of the transformers, in contrast to the others, was designed so that very little of the drip from the tank fell upon the bushings.

As mentioned previously, the coil insulation of some of the transformers did not receive a severe test. It seemed desirable to determine the effects of a more severe surge upon the windings of the transformers. Accordingly the insulation between the primary and the case on some of the transformers was tested up to the point of primary bushing flashover inside the case as listed in the table. No evidence of insulation damage was noted in these tests.

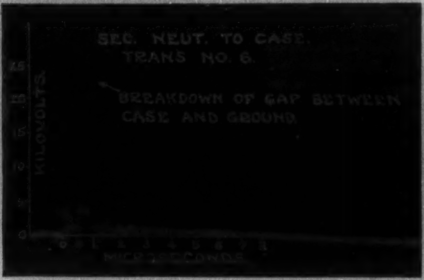

FIG. 7—OSCILLOGRAM SHOWING THE POTENTIAL BETWEEN THE CASE AND THE SECONDARY FOR THE TRANSFORMER WITH INTERNAL ARRESTERS DISCHARGING INTO THE CASE

Some tests were also made to determine the recovery value, if any, of punctured insulation as the result of the oil filling up the puncture. The two transformers, which in the previous tests had indicated breakdown between the secondary winding and the case, were subjected to surges up to the point of breakdown between the secondary and the case. The following values were obtained in this test.

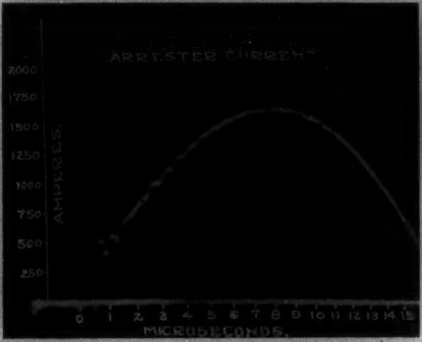

FIG. 8—ARRESTER SURGE CURRENT

| Transformer | Breakdown test secondary to case | Oil test |
|---|---|---|
| No. 2 | 56 kv | 24.8 kv |
| No. 3 | 17 kv | 25.5 kv |

These values would seem to indicate that a transformer in service might have its insulation punctured by a surge and still have sufficient insulation for normal line potential. If the transformer fuse is blown, there is necessarily some interval before it is replaced. This allows time for the oil to fill the puncture so that when the fuse is replaced the transformer continues to operate as before. Such has been the experience of many companies.

## CONCLUSIONS

1. With usual city conditions, consisting of a multi-

plicity of low resistance grounds on the secondary neutral, and the further possibility in some instances of a lightning arrester ground of high resistance, it has been demonstrated that the interconnection definitely limits transformer stresses to values which should reduce lightning failures to a practically negligible quantity, even with the older non-surge-proof types of transformers.

2. There should be a reasonable ratio between coil insulation puncture value, bushing flashover value on the inside of the tank and bushing flashover value outside of the tank.

3. Surge-proof transformers should have a reasonable factor of safety between insulation puncture strength and minimum bushing flashover values which should occur outside the tank to assure, in case of failure of protective equipment, that the transformer insulation will not be damaged.

4. Conclusion 3 represents the more or less ideal case. If extensive use of the interconnection results in reducing flashovers and punctures to a negligible number with non-surge-proof transformers, the added cost of the surge-proof type may be warranted only for special installations.

5. In general, reflections are produced across the series resistance of the surge generator discharge circuit depending upon the magnitude of the series resistance and the constants of and lengths of wire in the circuit. The magnitude of these reflections may be reduced by the capacitance of potentiometers, sphere gaps or the load itself.

6. The use of ultra-violet illumination of sphere gaps is conducive to greater accuracy and consistency of potential measurement, especially with potentials having steep-wave fronts and with the use of smaller spheres and gap spacings.

7. In making surge tests on transformers, the natural exposures will be most closely duplicated if surges are impressed between primary phase lead and grounded secondary neutral.

8. It seems likely that the insulation of transformer coils may be punctured by an impulse voltage and at a later time withstand line voltage.

### ACKNOWLEDGMENT

The authors appreciate very greatly the cooperation of the Utilities Research Commission and particularly the assistance of its committee of engineers of affiliated operating companies for whom Mr. D. W. Roper acted as chairman. Messrs. J. S. Malsbary and H. Creviston, graduate students, and several others who assisted in the routine testing and the analysis of data are complimented by the authors for their enthusiastic interest and cooperation.

R. W. WIESEMAN†
Member, A.I.E.E

and W. W. LEWIS†
Member, A.I.E.E

***Synopsis****—The problem of providing protection for rotating a-c machines against lightning overvoltages has two parts:*

*1. The protection of insulation to ground, which is mainly a question of the magnitude of the overvoltage, and*

*2. The protection of turn insulation, which is primarily a matter of wave front.*

*To meet the first requirement, the overvoltage to ground must be limited to a safe value. This is assumed to be approximately equal to the crest value of the 60-cycle high potential test. To fulfill the second requirement, the turn voltage gradient must be limited to conform to the turn insulation.*

*To secure these results, a protective scheme is proposed, which includes arresters 2,000 feet and 500 feet out on the line, or other means, to limit the incoming voltage to 2.5 times the crest value of the terminal arrester rating, a special arrester at the machine terminal to limit the voltage to the crest value of the machine high potential test, and a capacitor at the machine terminal to slope the wave front, thus limiting the turn-to-turn stresses. The capacitor also serves to limit internal overvoltages due to reflection at the neutral. For neutral grounded solidly or through resistance equal to or less than the combined surge impedance of the machine windings 0.1 μf capacitance is sufficient; while for isolated neutral, capacitance up to 0.5 μf may be necessary. Ground wires over the line for the initial 2,000 feet are recommended to protect against direct strokes.*

*For cases where the machine feeds the outgoing line through transformers, a special arrester is recommended at the machine terminals, to be connected in multiple with a capacitor, which in most cases may be 0.1 μf.*

* * * * *

## INTRODUCTION

THE behavior of traveling wave voltages in rotating a-c machines was discussed in two papers in 1930.[1,2] The principles of protection by means of arresters, capacitance and inductance were briefly outlined. In the ensuing two and a half years many of these principles have been studied further and some have been tried out in practise. It is the purpose of the present paper to present the results of certain of these studies and experiences and to offer a practical method for providing protection for rotating a-c machines against traveling wave voltages due to lightning.

The coordination schemes discussed in various papers at this convention are not generally applicable to rotating a-c machines, since the usual insulation used for this type of machine is of an entirely different order from the insulation of non-rotating apparatus, such as transformers, oil circuit breakers, bus bars, etc. A special treatment of the problem is necessary, therefore, to obtain a proper protective scheme.

## INSULATION CHARACTERISTICS OF ARMATURE WINDINGS

Rotating a-c machine insulation strength is influenced by the limitations of the dry type of insulation used, by space limitations, and by the types of insulation required to meet temperature and mechanical conditions.

These and other inherent characteristics of rotating machines make it difficult to incorporate high impulse strength in armature windings. Where transformers and similar apparatus are considered to have an impulse ratio in the general order of two or more, it appears that in view of the aforementioned factors, rotating machines should be considered to have an impulse ratio only slightly greater than unity. Thus, for the purpose of selecting protective equipment, safe practise will be adhered to by considering the crest value of the machine's one-minute high potential test voltage as the maximum value of impulse voltage which should be allowed on the coil or major insulation.‡

*Turn Insulation Impulse Strength.* The development of turn insulation of machines has been based on the normal voltage between turns and on operating experience. Under normal conditions, the turn insulation is subjected to relatively low voltages, ranging from 1 to 400 volts, but when a steep wave enters the winding, 100 to 1,000 times normal voltage may be impressed across the turns. Since it is not economical to insulate armature coil turns to withstand such steep wave voltages, and because it is feasible to protect the insulation normally in use, it appears rational to adhere to present insulation standards and to apply protective measures.

*Traveling Waves in Machine Windings.* It has been shown previously (reference 2) that an armature winding behaves similarly to an equivalent transmission line having a high surge impedance and a low propagation velocity. Fig. 1, based on tests on some medium and large machines, shows how the surge impedance and propagation velocity vary with rated terminal voltage. In the case of delta-connected or Y-ungrounded neutral machines, it is important to

‡Armature windings have a one-minute test voltage whose crest value is equal to $\sqrt{2}\,(2e + 1{,}000)$ where $e$ is the rated terminal-to-terminal rms voltage. The maximum allowable impulse voltage therefore is equal approximately to $3e$ for machines whose ratings are above 4,000 volts. If $E$ is taken as the crest value of the machine's terminal-to-terminal rating, the maximum allowable impulse voltage for the machine will be approximately $2.12E$.

know the time required for waves to travel from the line terminal to the neutral or midpoint of the winding, depending on whether the machine is connected Y or delta. This time may be expressed in micro-seconds and is referred to as microseconds length. Fig. 2, shows how the machine length varies with rating.

### Fundamentals of Protection

The problem of protecting rotating a-c machines may be divided into two major parts:

(A) The protection of turn insulation.

(B) The protection of major or coil insulation.

*(A) Protection of Turn Insulation.*

When a voltage wave enters an armature winding, it requires a small but definite time to travel around a coil. The voltage, Fig. 3, which occurs between adjacent turns depends upon the steepness of the entering wave and the length of the coil. This voltage appears not only across the turn insulation, but across the tier insulation as well if the coil is wound in tiers. Strand insulation and one-turn coils are not affected by this voltage. The maximum rate of voltage change (wave front) which a coil will withstand, depends upon the turn insulation and the turn length.

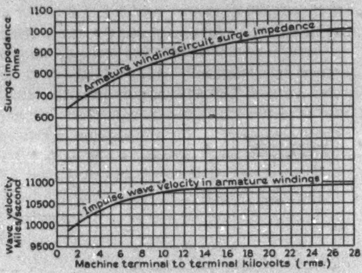

Fig. 1—Impulse Voltage Wave Characteristics of Medium and Large A-C Rotating Machines

It is obvious that by placing lumped capacitance to ground at the machine terminal, the capacitance will be charged through the surge impedance of the line by all waves arriving over the line (Fig. 3). The charging rate will depend upon the crest value of the incoming wave, the surge impedances of the line and machine, also the value of capacitance in microfarads. Knowing the characteristics of the machine and line, it becomes a relatively easy matter to determine the maximum rate of change (wave front) which can occur in the winding. Examination of a large number of machines indicates that in general 0.1 $\mu f$ (as a minimum) placed at the machine and with a limit placed on the applied wave, as will be given later, is sufficient to prevent excessive turn stresses. This criterion does not necessarily establish the total amount of capacitance which should be used at the machine, as it will be seen later that for other reasons a larger capacitance may be required.

This paper deals primarily with traveling wave voltages due to lightning. In some cases switching near the machine terminals may appreciably stress the turn insulation. This fact should be taken into consideration in applying the protection recommended.

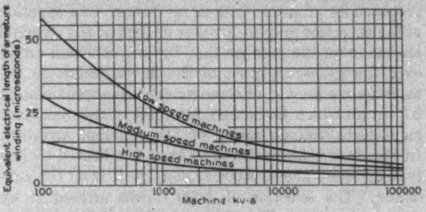

Fig. 2—Equivalent Electrical Length of Armature Windings of Medium Voltage A-C Machines

*(B) The Protection of Major or Coil Insulation.*

In general, the installations of machines in need of protection may be classified into two groups: first, machines directly connected to outgoing exposed feeders, and second, machines connected to exposed lines through transformers.

*1. Machines Directly Connected to Exposed Lines.* If a steep front long-tailed wave is allowed to enter the winding from directly connected exposed outgoing lines, the voltage-to-ground throughout the winding will depend on the machine connections. Fig. 4, shows voltages measured to ground on a 6,600-volt Y-connected machine when a ½-150 microsecond wave was applied to the machine over a line of 300 ohms surge impedance. It is to be noted that voltage to ground was measured for three conditions, namely; neutral grounded through a resistance equal to surge impedance of winding, neutral solidly grounded and neutral isolated. For the purpose of this study, the first two conditions may be grouped together. It follows, there-

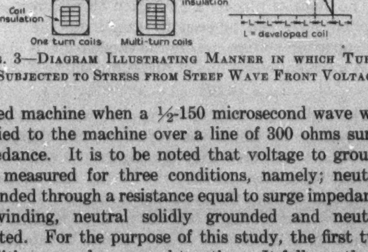

Fig. 3—Diagram Illustrating Manner in which Turns Are Subjected to Stress from Steep Wave Front Voltages

fore, that machines may be classified into two groups: (a) machines operating with their neutrals grounded (where the resistance at the neutral is equal to or less than the combined surge impedance of all windings), and (b) machines operating with their neutrals ungrounded ($R$ greater than $Z$), and delta-connected machines.

(*a*) *Grounded Neutral Machines.* The one-line diagram given in Fig. 5A shows the plan of protection proposed for grounded neutral machines. The selection of the capacitor and the arrester located at the terminal are made on the premise that the waves which arrive over the 2,000-ft section of the line adjacent to the machine are limited in some manner to approximately 2.5 $Ea$ (in which $Ea$ is the crest value of the maximum name-plate voltage rating of the terminal arrester). In Fig. 5A this limitation of voltage is indicated by line type arresters placed 2,000 ft and 500 ft from the generator. The selection of 2,000 ft was arrived at by theory and tests. This distance allows approximately 4 microseconds for the line arrester to operate before reflections from the capacitor reduce the incoming wave at the line arrester. This distance also makes it possible to utilize the surge impedance of the line between the line arrester and capacitor to obtain a charging rate for the capacitor.

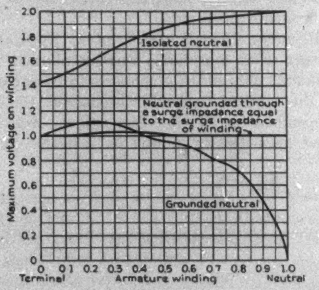

FIG. 4—MAXIMUM VOLTAGE-TO-GROUND ON A 6,600-VOLT Y-CONNECTED ARMATURE WINDING WHEN A 0.5/150-MICROSECOND IMPULSE WAVE IS APPLIED

The value of placing a limitation on the crest of the applied wave can be seen by examining the formula for capacitor voltage, where the capacitor $C$ is charged by a wave $E_1$ over a line of surge impedance $Z_1$.

$$e_c = 2E_1\left(1 - \epsilon^{-t/Z_1C}\right)$$

The higher the crest of the applied wave, the higher the voltage to which the capacitor will charge. It should also be noted that the higher the crest of the applied wave, the greater will be the rate of charge (steepness of wave front) on the capacitor. It follows, therefore, that placing a limitation on the applied wave is a matter of economics. Since the cost of capacitance increases approximately as the square of the voltage rating, it is apparent that for the higher voltages it is desirable to keep the required capacitance small.

Hence, for the higher voltage grounded neutral machines, it will be more economical to use small capacitance of the order of 0.1 $\mu$f (to prevent turn stress), in parallel with an arrester, which will limit the crest value of the entering wave below 2.12$E$, than to use large capacitance without the arrester in parallel. This type of protection can be used because no positive voltage reflections occur at the neutral when the neutral resistance is equal to or less than the combined surge impedance of the windings. For low-voltage machines, where the capacitor costs are not so high, the use of a large capacitor dispenses with the need of an arrester in parallel.

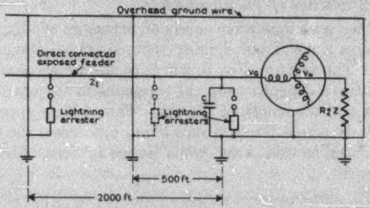

FIG. 5A—SCHEME OF PROTECTION FOR GROUNDED-NEUTRAL MACHINES

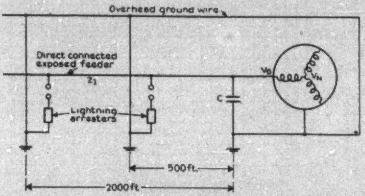

FIG. 5B—SCHEME OF PROTECTION FOR UNGROUNDED-NEUTRAL MACHINES

(*b*) *Non-Grounded Neutral or Delta-Connected Machines.* The problem of protecting ungrounded neutral (Fig. 5B), or delta-connected machines, is much more difficult than that of protecting machines whose neutrals are grounded. This is obvious when we consider that a machine winding may have a length of 50 microseconds and the reflection point for the waves may be 50 microseconds removed from the point of voltage limitation. It is also apparent that where the waves which enter the winding may reflect approximately to double value at the neutral, the entering voltage must be held at the line terminal to one-half the allowable machine impulse voltage (2.12$E$). The difficulty of this problem can further be appreciated when we consider the fact that the crest value of the operating voltage is $E$, and that in order to prevent positive reflections from exceeding the allowable impulse voltage, any device which is placed at the terminals to limit the incoming wave must hold the voltage to 1.06*E*.

Since our present day arresters cannot operate between such narrow voltage limits, some other means of obtaining lower impulse voltages must be used. It is apparent that by placing a limit on the impulse voltage which could reach the machine from the line, and by placing a sufficiently large lumped capacitance at the machine terminals to ground, the capacitance will act to reduce the impulse voltage.

For the purpose of calculating the value of this capacitance, it has been assumed that the average installation will consist of a double-circuit three-phase line, whose combined surge impedance is not less than 250 ohms per phase. It is further assumed that the voltage which is allowed to pass the line arresters over the 2,000-ft section adjacent to the machine is a 0/40 microsecond wave, whose crest value is 2.5*Ea* and that waves arrive simultaneously over each of the six conductors.

The 0/40 microsecond wave was selected as fairly representative of the most severe waves met in practise. The sheer front was chosen to simplify the calculations by eliminating one term from the equations.

Fig. 6 is a plot of the voltages which occur at the machine terminal and also at the isolated neutral for various values of capacitance at the machine terminals. These curves indicate that for the assumed set of conditions 0.5 $\mu$f will, in general, offer sufficient reduction in the voltage at the terminal to prevent overstressing the machine insulation throughout the winding. These assumed conditions apply to a single-circuit winding. If the machine has a multiple circuit winding or there are multiple machines, the voltage will be lower than indicated by the curves.

The exact determination of the capacitance required is more important from an economic standpoint in the case of machines which are in the 12- and 15-kv ratings, or higher, as these are the ratings at which capacitor costs are relatively high. It is obvious that the larger the capacitance in microfarads, the greater will be the margin of protection to the machine, and where a large capacitance can be obtained without substantial increase in cost, it is advisable to use larger capacitance.

It should be noted in this set of curves that the machine length is given in microseconds time required for voltage to traverse the windings, and that the curves are plotted for machines whose lengths *L* vary from 10 to 40 microseconds. For a given value of capacitance at the machine terminals, the resulting voltage at the neutral depends on the length of the winding up to a length where 100 per cent reflection of the entering wave occurs. Lengths greater than this would not increase the value of reflected voltage.

### OVERHEAD GROUND WIRES

It has been pointed out that the selection of the protective equipment located at the terminals of the machine is based on the assumption that the incoming surges are limited to 2.5*Ea* for a distance of at least 2,000 ft from the machine. In regions where direct strokes are frequent, overhead ground wires should be located over the 2,000-ft section of line. The effects

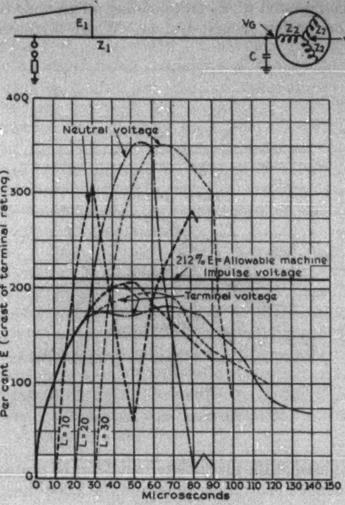

FIG. 6—A

VOLTAGES WHICH OCCUR AT MACHINE TERMINALS AND AT NEUTRAL OF AN ISOLATED-NEUTRAL MACHINE WITH A 0/40-MICROSECOND IMPULSE WAVE OF 2.5*Ea* ARRIVING AT THE MACHINE. MACHINE LENGTHS *L* VARYING FROM 10 TO 40 MICROSECONDS

$Z_1$ = 250 ohms, $Z_2$ = 800 ohms
$C$ = 0.12 $\mu$f

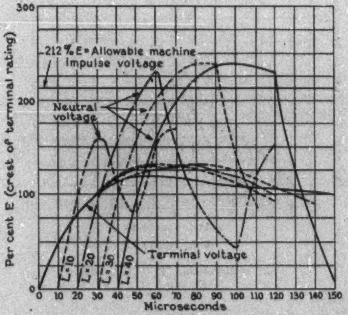

FIG. 6—B

$Z_1$ = 250 ohms, $Z_2$ = 800 ohms
$C$ = 0.3 $\mu$f

of arrester ground resistance can be largely overcome by connecting the arrester grounds, the capacitor grounds and the machine frames together with the overhead ground wires, and bonding all grounds to the common station ground system. Where a station arrester is used at the machine terminal for the protection of a grounded neutral machine, and the 2,000-ft section is protected by overhead ground wires, as suggested, it should not be necessary to install the line arrester at 500 ft from the generator (Fig. 5A).

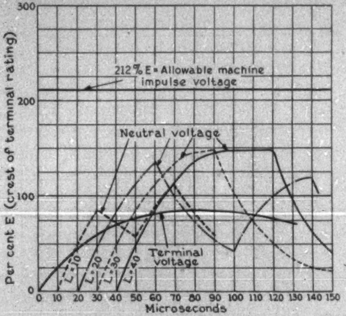

FIG. 6—C

$Z_1 = 500$ ohms, $Z_2 = 800$ ohms
$C = 0.3\ \mu f$

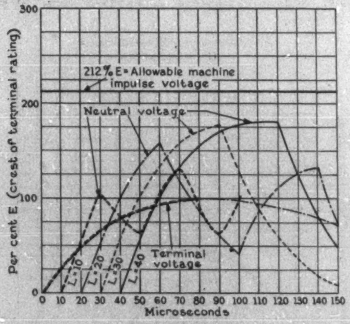

FIG. 6—D

$Z_1 = 250$ ohms, $Z_2 = 800$ ohms
$C = 0.5\ \mu f$

## INDUCTANCE AT MACHINE TERMINALS

It would be possible to remove the necessity for limiting the line voltage at approximately 2,000 ft out on the exposed lines, by inserting an inductance in series with the machine and placing a capacitor to ground between the machine and the inductance. It is necessary, however, to place an arrester on each side of the inductance to prevent the voltage resulting from oscillations between the lumped capacitance and the inductance from exceeding 2.12*E*. This plan has not proved practical up to the present time, and it seems that the alternative plan proposed has certain advantages which are applicable to the problem of protecting machines in general.

## PROTECTION OF MACHINES CONNECTED TO LINES THROUGH TRANSFORMERS

Messrs. Palueff and Hagenguth have shown the mechanism by which surges are transmitted through transformer windings.[3] Examination of their solution discloses that for YY-connected transformers with both neutrals grounded, the electromagnetic component of surge voltage which may be transmitted through to the machine windings should be dealt with by reducing the (upper) circuit shown in Fig. 7 to that shown below where *L* in henrys is obtained from the transformer short-circuit reactance as measured from the low-voltage side and the surge impedance of the line is reduced to its proper value, that is, by multiplying the surge impedance on the high voltage side by $\left(\frac{1}{r}\right)^2$, in which $r$ is the ratio of high-tension to low-tension turns.

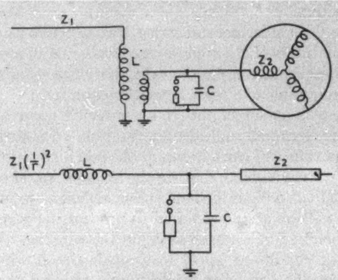

FIG. 7—PROTECTION OF MACHINES CONNECTED TO LINE THROUGH TRANSFORMERS

Upper—Actual circuit
Lower—Equivalent circuit

YY transformers with both neutrals grounded constitute the only connection for which the waves transmitted to the machine cause positive reflections of voltage at the machine neutral. Under these conditions sufficient capacitance must be used to prevent reflections at the isolated generator neutral from exceeding 2.12*E*. The voltage which may be transmitted through the transformer depends upon a number of factors, such as kilovoltamperes, reactance, ratio of transformation, etc., and it is therefore necessary to examine each case to determine the amount of capacitance required.

For all other transformer connections, the voltages due to the waves which are transmitted into the machine windings cancel when the waves arrive at the machine neutral, hence, for protection to the machine it is only necessary to limit the crest value of the entering waves and to prevent sudden voltage changes (steep waves) which would cause excessive turn stresses. Examination of a number of cases indicates that by placing 0.1 μf capacitance or more in parallel with the proper arrester between transformer and generator, this protection will be accomplished.

The capacitor which is placed in parallel with the arrester has two useful purposes: first, it aids in sloping off steep waves and, second, it reduces the crest value of the entering wave where the impressed wave is not of sufficient severity to charge the capacitor to the voltage required for arrester operation.

### CONCLUSIONS

This paper outlines a rational method of providing protection for rotating a-c machines from surge voltages caused by lightning and originating on exposed transmission lines.

Machine characteristics are indicated which influence the proper selection of protective equipment.

The plan of protection involves a limitation of the voltage of the applied wave to 2.5 times the maximum name-plate rating of the terminal arrester for a distance of at least 2,000 ft from the machine, and the use of special arresters and lumped capacitance at the machine. Capacitance of 0.1 to 0.5 μf may be necessary, depending on whether the machine neutral is grounded or isolated.

Overhead ground wires should be placed over the exposed line to a point at least 2,000 ft out from the station to protect this section of line against direct strokes.

Where the rotating machine is connected to the exposed line through a transformer, a special arrester and a capacitance of 0.1 microfarad or greater in parallel should be located between the transformer and machine.

Breakdown of machines is probably a progressive process and if the suggested protective means are not applied until the machine has been in operation for some years, the anticipated results may not be fully realized.

### ACKNOWLEDGMENT

The authors wish to acknowledge the valuable assistance of Mr. H. G. Brinton in the mathematical analysis connected with this problem and in the preparation of the appendix, which follows:

## Appendix

The voltage at the machine neutral was calculated by superimposing the original entering wave and the various reflections in their proper time relation. The first entering wave is completely reflected at the neutral and travels back to the terminal, where part passes out and part is reflected back into the machine with reversal of sign, and becomes what we may call the second entering wave. This wave enters $T$ seconds after the first wave, where $T$ is the time required for a wave to travel twice the length of the winding from terminal to neutral or point of complete reflection. In the same way there is a succession of entering waves at intervals of $T$ seconds, each being opposite in sign to the preceding one. Each wave produces double its voltage at the neutral or point of complete positive reflection, and the total voltage at that point is the sum of the voltages due to the several entering waves added at the proper time intervals.

The voltage at the machine terminal is also the superposition of a number of voltage waves impressed at intervals of $T$ seconds. However, these voltage waves are easily determined if we know the various entering waves. The first terminal voltage wave is equal to the first entering wave. The second terminal voltage wave is equal to the sum of the first and second entering waves (which are opposite in sign). The $n$th terminal voltage wave is the sum of the $n$th and the $(n-1)$ entering wave.

Thus, for the present purposes it is only necessary to obtain formulas for the various entering waves in order to determine the total voltage at the terminal and the neutral at a given instant. It is not necessary to take space for the derivations here.

To obtain the voltage waves for the several machine lengths examined, the various entering waves were first plotted and then added in their proper time relationship, depending on the length of machine assumed. The formulas follow:

$E = E_1 \epsilon^{-Bt}$ = wave on line
$B$ = 0.0173 for a 0/40 wave
$Z_1$ = surge impedance of incoming line
$Z_2$ = surge impedance of machine
$C$ = capacitance in microfarads at machine terminal
$L$ = time in microseconds required for a wave to travel the length of the machine winding
$V_G$ = voltage at machine terminal
$V_N$ = voltage at machine neutral
$V_{1e}, V_{2e}, V_{3e}$ = first, second, third entering waves
$t$ = microseconds from beginning of each wave.

Let

$$A = \frac{Z_1 + Z_2}{Z_1 Z_2 C}$$

$$K = -\frac{2}{B - A}$$

$$M = Z_1 C$$
$$D = Z_2 C$$

$$S = \left(\frac{K}{D} + 1\right)$$

$E_1 = 100$ per cent

$$V_{1e} = V_{1G} = \frac{K}{M}\left(\epsilon^{-At} - \epsilon^{-Bt}\right)$$

$$V_{2e} = -\frac{K}{M}\mathrm{S}\left(\epsilon^{-At} - \epsilon^{-Bt}\right) + \frac{2K}{M}\cdot\frac{t}{D}\epsilon^{-A}$$

$$V_{3e} = \frac{K}{M}\mathrm{S}^2\left(\epsilon^{-At} - \epsilon^{-Bt}\right)$$

$$-\frac{2K}{M}\left(1+\mathrm{S}\right)\frac{t}{D}\epsilon^{-At} + \frac{2K}{M}\frac{t^2}{D^2}\epsilon^{-At}$$

$$V_{4e} = -\frac{KS^3}{M}\left(\epsilon^{-At} - \epsilon^{-Bt}\right) + \frac{2K}{M}\left(1+\mathrm{S}+\mathrm{S}^2\right)\frac{t}{D}\epsilon^{-At}$$

$$-\frac{2K}{M}(2+\mathrm{S})\frac{t^2}{D^2}\epsilon^{-At} + \frac{4K}{M}\cdot\frac{t^3}{3D^3}\epsilon^{-At}$$

$$V_{5e} = \frac{KS^4}{M}\left(\epsilon^{-At} - \epsilon^{-Bt}\right) - \frac{2K}{M}\left(1+\mathrm{S}+\mathrm{S}^2+\mathrm{S}^3\right)\frac{t}{D}\epsilon^{-A}$$

$$+\frac{2K}{M}\left(3+2S+\mathrm{S}^2\right)\frac{t^2}{D^2}\epsilon^{-At}$$

$$-\frac{4K}{M}\left(3+S\right)\frac{t^3}{3D^3}\epsilon^{-At} + \frac{2K}{M}\cdot\frac{t^4}{3D^4}\epsilon^{-At}$$

Formulas for further entering waves, if desired, may be written out from inspection of the preceding formulas.

**F. F. Brand:** The interesting time lag curves, given in Mr. Vogel's paper and more completely in the paper by Messrs. Montsinger, Lloyd and Clem, which show the relation of insulation and various gaps, are apt to give the impression that the whole scheme of insulation coordination which has been recommended by the A.I.E.E. Transformer Subcommittee is of little value, since the dielectric strength of the point gap which has been standardized increases more rapidly than that of solid insulation for very short time lags.

A careful consideration of the basis, on which coordination of insulation has been worked out, shows that one cannot form a general opinion merely from these time lag curves. Primarily coordination of insulation was started to form a basis for the relation of power transformer insulation to that of the rest of the circuit, for those transients which these transformers should be expected to withstand when connected to overhead circuits.

The time lag curve shown by Mr. Montsinger indicates that an insulation barrier, which has a 10 per cent margin of dielectric strength over a point gap of a given setting for wave fronts of 2 microseconds or more, will fail if a wave with a front of less than ¾ microsecond and of sufficient voltage to break the point gap is impressed on it.

Effective coordination implies a factor of safety in actual transformer insulation with which the transformer has not been credited in this curve.

Secondly, for power transformers at least, it is very doubtful if they will be subjected to waves of less than 1 microsecond front. The coordination point gap settings for these were worked out on the basis that they would be placed close to the transformer but interposed between it and the line over which the transients were expected to flow.

Any stroke on the line, whether induced or direct, which has a voltage of the order of the coordination gap breakdown is above the corona point of the line, and the wave front is therefore sloped by losses as the wave is propagated toward the station. In addition to this, the wave front on arriving at the station is sloped by the lumped capacitance of the station apparatus and connections.

It appears, therefore, that a wave front of ¾ microsecond or less, which the time lag curve shows might be dangerous to transformer insulation can appear only at the transformer terminals, not by reason of direct strokes on the line, but actually at transformer terminals unprotected from such strokes by grounded metal such as overhead ground wires, steel work, or direct stroke masts.

Furthermore, it appears that the rate of voltage rise in the rare event of a direct stroke striking the transformer terminals, due to the enormous voltage of the lightning stroke, would be such that any gap, even a few feet away, might not receive anything like the same voltage in a fraction of a microsecond as that received by the transformer terminal struck. The type of gap, therefore, might have little effect in preventing excessive voltage on the transformer in such cases. Good engineering practise would obviously seem to demand that valuable apparatus such as power transformers should be shielded effectively from direct strokes to their terminals.

**C. L. Fortescue:** The title of the impulse testing paper is very satisfactory. The writer feels that on such an important matter as the impulse testing of apparatus it was advisable to proceed with caution for the reason that while a great deal of data have been obtained during the past five years with regard to surges produced by lightning on transmission lines, there has not been time enough yet fully to digest these data.

There has been a tendency to treat the subject of coordination of insulation in apparatus and system as if it were an entirely new approach to the solution of the economic protection of power systems. For this reason suspicion might very well be created in the minds of some of our system engineers that the development of the principles of coordination might lead to the throttling of initiative in the design and layout of electrical systems. It is very vital that this impression be prevented.

In discussing the paper by Messrs. Montsinger, Lloyd and Clem the writer points out that it is possible to protect the transmission and connected substation so that the line surges resulting from lightning due to direct or induced strokes will be reduced at their source so that what enters the substation will relatively be innocuous.

It would seem logical for a system carefully laid out and well protected to use apparatus in the substation requiring a lower impulse test specification. It also seems logical that the manufacturer should have the privilege of recommending what class of insulation may be used with different levels of protection of line and station. Otherwise the principle of coordination (which I take to mean the application of sound engineering and economic principles to the protection and insulation of power systems so as to produce continuity of service at a minimum cost) would have no meaning.

There will naturally be some differences of opinion among transmission engineers as to the application of these principles especially in the case of 220-kv systems, some favoring the use of lightning arresters to maintain continuity of service by preventing spillover of the gap and others being in favor of using a higher level of insulation with correspondingly higher gap setting leaving out the arrester. I, myself, believe that the best protection and the one that insures continuity of service at all times will use an approved type of lightning arrester in multiple with the gap.

The subcommittee that has been working out the methods of carrying out impulse tests on transformers is to be congratulated in having developed a logical and satisfactory technique for carrying out such tests especially the ingenious method of applying power follow up, which insures that if any damage occurs to the transformer as a result of the application of the impulse it will show up positively.

Mr. Vogel's paper presents the results of a series of tests to determine the approximate impulse time lag characteristics of insulation of the type used in transformers. As he points out, these characteristics do not necessarily apply to an actual transformer because the impulse stresses in the transformer will depend upon its physical design, that is to say, whether the principles of coordination have been properly carried out in the insulation of the coils and coil groups in the transformer design. Where these principles have been properly carried out the impulse time lag characteristics of the transformer as a whole will closely approximate that of the major insulation as shown in Mr. Vogel's paper. The data given in Mr. Vogel's paper therefore are of great value to transformer manufacturers.

The data presented comparing surge strengths of insulators, gaps, bushings, and transformer major insulation are of great value. It is interesting to note how convenient these impulse time lag curves are as a basis of comparison between insulators having different impulse time lag characteristics. The writer is convinced that if the proposed basis of comparison of minimum flashover and puncture curves for different standard waves had been adopted the result would have caused a great deal of confusion. The impulse time lag curves are all the fundamental data needed for coordination and the use of the 1-5 and 1-10 waves should be confined to shop and laboratory investigations.

A critical examination of these impulse time lag curves at once suggests the advisability of obtaining a coordinating gap that has an impulse time lag characteristic corresponding more closely to that of the major insulation. This at once suggests the sphere gap with close spacing between spheres. Certainly transformers connected to systems unprotected by ground wires where direct strokes may occur close to the station should be coordinated for short time lags, however, if the proper type of lightning arrester always is used in multiple with the gap such coordination is satisfactorily obtained and the arrester does away with the possibility of flashover of the terminal.

It is interesting to note that the major insulation adopted for transformers in the past which met the requirements of the standard A.I.E.E. tests also met the requirements of coordination in the higher voltage classes. As discussed later these test specifications with the necessary insulation to meet them were obtained in the past as a result of experience with practically no knowledge as to the formation and propagation of surges due to lightning and it is surprising how well these tests met practical requirements in service. With the data now available and their further analysis and with the improvements in design and testing of power transformers we should look forward to a radical improvement in their operating performance in the future.

The paper by Messrs. Montsinger, Lloyd and Clem contains a great deal of valuable information in connection with the subject of coordination of the insulation of apparatus in substations to withstand the surges that enter the substation as a result of switching or lightning. One is tempted to ask what is meant by the term coordination as used in this connection. Certainly the opening paragraph of the paper attempts to define its meaning, but it seems inadequate. It seems that what is meant is nothing more than sound engineering in applying the data and knowledge that are available to obtain a layout that will give reliable service at the least possible cost. Coordination must be carried out therefore in such a way that flashover of coordination gaps is comparatively rare. One way to do this is to use lightning arresters to protect the gap against flashover, in which case the gap may be considered as back up protection to the arrester. Another way is to raise the insulation level of the whole station layout and protect against it at its source in the line by adequate ground wire protection.

In the past the knowledge and data that have been obtained in the last five years on lightning surges were not available, very little also was known as regards switching surges and even today we probably know less about switching surges than we do about those due to lightning. As a result the engineering of transmission lines substation and apparatus insulation was largely statistical. Lightning arresters were developed to a limited extent and no doubt played a part in protecting apparatus. Fortunately the impulse strength of the substation insulation of the early installation generally was below that of the line and apparatus so that the insulators performed the functions of a coordinating gap and usually saved the apparatus from failure. It is surprising how well the apparatus insulation arrived at by this rough and ready engineering has stood up in the past, in fact we are compelled to admit that there was some degree of coordination carried out between apparatus insulation and substation insulation even in those days when reliable data as to surge magnitude were lacking.

The principle of coordination should not be considered as applying solely to the station apparatus and its insulation level, which may be determined by a so-called coordinating gap, but extends nowadays to the whole system. Thus in the transmission line the overhead ground wire is the relief measure in coordination of the transmission line insulation, and the configuration of the ground wires with respect to the line wires must be such as to shield them effectively from an oncoming stroke and the distance between ground wire and line wire must be coordinated with the span length the surge impedance of tower and footing or buried counterpoise so as to prevent side flash. The line insulation and the clearance from towers under wind conditions must be coordinated. It may not be economic to design the line so as to be lightning proof, but it may be coordinated for a certain level of protection and sufficient data are now available to enable the designer to predict with reasonable accuracy the performance of a line designed for a given level of protection. The computations for determining the ground wire spacings and tower insulation clearance for a given level of protection are simple, all the necessary data having been systematized.

With respect to the protection of the station against direct strokes, the problem is simpler even than for the line, for the line runs over very rough territory where low footing resistances are difficult to obtain and spans are long and towers high. Recourse must then be had to a counterpoise connected to the tower footing and more liberal insulation and tower clearances all of which are expensive when long distances have to be considered. In the case of stations the area to be considered in connection with the overhead protective measures is comparatively small, the supporting structures are close together so that even when the resistivity of the earth is high a very effective ground can be obtained by a buried grid connecting all the support footings. The supporting structures need not be high and therefore the surge impedance will have a slight effect in raising the potential at the top of the ground wire support when struck. Since the structures are close together the potential at the middle of the ground wire span will be kept at a low value when struck so that the clearances between it and the bus structure need not be very great. In calculating the surge to which a transformer may be subjected as a result of a direct stroke at a ground wire between two supports, we must compute the potential at each point of the ground wire between supports during the duration of the stroke and consider the capacity coupling between line and ground wire between supports as the medium by which the surge on the ground wire is conveyed to the line and thereby to the transformer, the surge impedance of the line and the capacitance of the transformer are in multiple.

It will readily be seen that since the capacity of the transformer is large compared to the coupling capacity between supports in representative cases, a very small part of the potential of the ground wire appears across the terminal of the transformer, probably not enough to operate the arrester or coordinating gap. In the case of the transmission line itself when a ground wire is struck, provided the protection is effective, no surge will appear on the line though its potential will be raised at the point of stroke and will die out as the surge on the ground wire reaches successive adjacent towers; after the second or third tower the reduced potential is negligible. Even when the ground wire protection is inadequate the surge that appears on the line due to its failure is limited to waves of steep front chopped by the insulator of the line which alternates very rapidly as this travels along the line.

It is practicable therefore to protect a transmission system and connected stations so that the probability of a surge of sufficient magnitude entering the stations is very small, but it is nevertheless always advisable to install coordinating gaps. There are today some high voltage systems without lightning arresters which have been in operation in lightning territories for five years without experiencing spill-over due to lightning; which is a practical proof of the soundness of the above statement. This degree of protection may be justified economically on 220-kv systems and higher, but not so for 138-kv supplies and below, except for very special cases. For these low voltage systems lightning arresters as well as coordinating gaps should be used.

It is noted that in order to show the complete coordination between insulation, gaps, etc., volt-time curves on the 1½-40 wave on a common sheet have been used. This departure from the authors' former contention that coordination data should be presented in terms of several of different lengths and steepness such as the ½-5, 1-10 and 1½-40 is very gratifying, since the writer has always insisted that the impulse time lag characteristics are fundamental data and fully determine the coordination characteristic of every type of insulator. The impulse time lag curves presented were obtained by using the 1½-40 wave which is convenient since it has been adopted by the transformer committee for all tests on transformer. It would be advantageous if a wave as nearly perpendicular as possible could be used for impulse curves, for the reason that flashover on the front makes the impulse ratio higher than it should be and therefore exaggerates the steepness of the curve at the short time lags. Such a wave chopped at a suitable time would be quite as suitable as the ½-5 and the 1-10 wave and by adding resistance in series with the chopping gap can be made to duplicate these waves for all practical purposes. We have used impulse time lag curves to coordinate the insulator and clearances of towers for potentials that appear as the result of direct stroke and also checked them in the laboratory by artificial waves corresponding to these potentials; the results have tallied closely enough for practical purposes.

**F. W. Peek, Jr.:** A year ago the writer suggested that the Institute appoint a committee to formulate rules for impulse testing of transformers. The rapid progress that has been made is indicated by the papers presented. The writer made the suggestion at that time that "one of the most important problems in establishing lightning tests is to devise means for detecting incipient turn-to-turn, coil-to-coil or other failures. This is so because the operator must feel assured beyond any reasonable doubt that the transformer is as good after the test as before the test was made." This is true particularly if the windings can oscillate. It would be worth the committee's while to give considerable attention to this subject. As matters stand at present, it cannot be said that impulse testing is a very accurate measure of the worth of a transformer.

For example—assume that three different types of transformers ($A$, $B$, and $C$) are given impulse tests. Assume further that $A$ fails through the major insulation but that $B$ and $C$ apparently pass the test. It might well be that $B$ was damaged and that $C$ actually passed the test because it was properly designed. In this case the test without a detector is worse than useless. The real deciding factor still rests in the knowledge and experience of the designer in such matters. This, of course, also applies to 60-cycle testing, but fortunately this test is made over a sufficient interval of time so that, usually, damage can readily be determined. In fact, this can be done with great certainty by an instrument or detector called the "coronaphone"[1].

Impulse testing voltages should bear a definite relation to the voltages that are permitted upon transmission lines by the insulators, coordinating gaps and arresters. For practical purposes lightning voltages may be divided roughly into three classes: *direct strokes; traveling waves;* and *transients of internal origin such as switching surges.*

*Direct stroke voltages* for the purpose of this discussion are those that occur directly to the terminals of the apparatus and are most severe because they are exceedingly steep and may reach high values before the insulators or ordinary gaps have had a chance to spark over. The chance of strokes occurring directly to apparatus terminals is not great even when special protective means are not provided. Fortunately, by certain protective schemes direct stroke voltages, as defined above, may readily be prevented. In fact, most direct stroke voltages are converted into voltages of the traveling wave type before reaching apparatus.

The *traveling wave type of voltage* has a more sloping front than the *direct stroke type* and may be the result of induction; the residual of a direct stroke to the line left by insulator sparkovers a few hundred feet away; or a direct stroke near a station well protected by ground wires or lightning rods. Not all these voltages are true traveling waves but are included in this type because of their effects.

The *only important effect of voltages of internal origin* is on the setting of protective apparatus. Such apparatus must be adjusted so that voltages of this type are not continually causing sparkover.

There are several papers in this session that treat of the effect of coordination on transformer insulation. The following discussion is confined principally to the paper by Messrs. Montsinger, Lloyd and Clem because the data given on insulations are very complete and cover the whole range from switching surges to direct strokes.

An examination of Fig. 2 in this paper shows that insulation strength does not vary greatly until the time is decreased to about 2 μsec for the method used. This method is referred to later. The strength then begins to increase appreciably. The figure also shows that the coordinating rod gap likewise begins to increase rapidly at the 2 μsec point. Although both the insulation and the coordinating rod gap increase in strength with decreasing time, the sparkover voltage of the gap increases much more rapidly than the strength of the insulation. These characteristics show that the rod gap is quite ideal for the usual lightning voltage but that the margin decreases for the direct stroke type. Any desired margin can be maintained with the rod gap when ground wires or other protective means are used to reduce the direct stroke of voltage to the traveling wave type. An alternative scheme is to use a gap with characteristics of a sphere or to reduce the rod gap setting somewhat. It should be pointed out that Fig. 2 does not represent a transformer but shows the general characteristics of an insulation barrier. There is no constant impulse ratio or relation between 60-cycle and lightning voltages for transformers. The writer has observed many tests on all types of barriers and transformers. It is possible for a transformer to have sufficient margin to be quite satisfactory for rod gap coordination. These curves do not condemn the rod gap as a coordinating gap. Incidentally, it is of interest that Mr. Vogel's data are in agreement with those of Messrs. Montsinger, Lloyd and Clem up to 2 microseconds. Further comparison is not possible.

---

[1] *General Electric Review*, January 1929, Vol. 32, No. 1, page 45.

It is pointed out that 2 microseconds does not represent a critical time interval when insulation characteristics suddenly change as Mr. Vogel suggests. The appearance of 2 microseconds as the point where characteristics change is brought about largely by the manner in which the tests are made. These tests were made by applying a 1½-40 wave at different voltages and noting the time at which failure occurred. At 2 microseconds the crest has practically been reached and a shift occurs from the tail to the front of the wave and the effective time interval thus becomes suddenly greatly reduced. There is a transition from tail sparkover to front sparkover. Thus, these are not true voltage time curves and are misleading. The effect of this type of test is equivalent to the ½-5 wave at approximately 1.5 microseconds point in Fig. 2.

It may be concluded from the above that the most effective protective system is: insulation levels as fixed by the coordinating rod gap values; protective means, largely in the way of ground wires extending at least a few poles out from the station or towers for converting the direct stroke voltages into the traveling wave type voltages; and lightning arresters. It may be desirable sometimes to add a gap of sphere gap characteristics, particularly where ground wires are not used.

**H. V. Putman:** There has been considerable misunderstanding on the part of some operating engineers regarding the work of the Transformer Subcommittee of which the writer is chairman. They have felt that the committee has been trying to tell them how they should establish insulation coordination in their substations, what level of insulation they should use on their lines, and what level of insulation they should require in their transformers. This is not the purpose of the committee at all. We feel that the general problem of insulation coordination largely is outside the scope of the committee's activities. The joint NEMA-NELA committee on insulation coordination is, we believe, the proper body to handle this broad, general problem of insulation coordination. It is only one small part of this problem affecting the transformer proper which we are endeavoring to handle, and even here we are not attempting to tell operating engineers how much or how little surge strength they should have in their transformers. We are endeavoring to bring order into our design procedure, to make it possible for a manufacturer to supply intelligently a transformer having specified impulse strength and to prove definitely that that impulse strength has been obtained.

Surely in carrying out any plan of insulation coordination which may finally be agreed upon, it will be necessary to know and prove the impulse strength of every piece of apparatus entering into the coordination scheme. The committee wants to remove any uncertainty regarding the impulse strength of transformers. It wants to know and prove the impulse strength of transformers so that they may intelligently be fitted into any scheme of coordination desired.

So far as our committee is concerned, operating engineers are perfectly free to choose the level of insulation which they desire in high voltage transformers. The writer has talked to some operating engineers who felt that certain transformers, because of the unusual importance of their application to continuity of service, should have higher impulse strength than normal, and that standards of at least two different values of impulse strength should be established for each voltage class. The writer is very sympathetic to this view, but it is a matter outside the scope of the subcommittee's activities.

It is true that the subcommittee has established a schedule of coordinating gaps for different voltage classes, but this has been done not to dictate apparatus or line insulation levels, but only to indicate or specify what impulse strength may reasonably be expected in well designed transformers meeting the existing A.I.E.E. tests. It is true also that in extending this schedule of coordinating gaps to the distribution circuit voltages in a manner consistent with the gaps established for the higher voltage classes, it became apparent immediately that the existing A.I.E.E. tests for these lower voltages were much too low and should be raised. Experience also had indicated the same thing and had brought about increases in the insulation actually employed by several manufacturers over and above that required by the A.I.E.E. tests. The subcommittee therefore is considering recommending the low frequency A.I.E.E. tests in these lower voltage classes be raised to make them consistent with the coordinating gaps which have been established and with field experience.

The schedule of coordinating gaps for the different voltage classes established by the subcommittee now extends from ¾ in. for the 600-volt class to 64 in. for the 220-kv class, and represents the best standard for insulation strength available today. Apparatus designed to test against these gaps in line with the subcommittee recommendations for impulse testing will meet the existing low frequency A.I.E.E. tests in the higher voltage classes and the proposed increased tests in the lower voltage classes. The writer personally recommends (not speaking for the subcommittee), that those who are engaged in this broader problem of insulation coordination accept the subcommittee schedule of coordinating gaps as the normal insulation level of transformers in the different voltage classes, and if it can be agreed that certain transformer applications, because of their relative importance, require higher or lower insulation than normal, then the insulation level and test be that corresponding to the next higher or lower gap in the schedule.

In conclusion reference is made particularly to the changing attitude of the industry toward the matter of impulse testing. When this problem was assigned to the subcommittee at the winter convention of 1932, grave doubts were expressed as to the feasibility of impulse testing. In one of the papers presented at that time, the statement was made that there was no way to detect damage due to impulse testing except by complete dismantling and examination of the insulation piece by piece. It is surprising to hear that same thought again voiced by Mr. Peek in his statement that the subcommittee has not arrived at any satisfactory solution to the detection problem. In the writer's discussion at the winter convention last year it was stated that impulse testing was practical and failures could be detected. These statements were based on the work of Mr. Vogel in developing impulse testing with dynamic power connected and with the surge synchronized with the crest of the voltage wave. Since then Mr. Vogel's work has been published and the subcommittee has adopted this method in its recommendation. The progress report of the subcommittee leaves little doubt about the feasibility of impulse testing, or little question about the matter of detection of failures.

If Mr. Peek actually does experience these pinhole failures which he and his associates have mentioned so often in connection with surge testing, there must be some peculiarity in his design practise which is responsible for this, because in our experience we have never found pinhole failures except as a secondary result of a major breakdown. We have always been able to detect any failure during the surge test by the method outlined in the concluding paragraph of the progress report of the subcommittee. But more important, every transformer in which no damage was detected by the proposed method, when torn down, was found to be absolutely clean—and we have looked for these pinhole failures with magnifying glasses.

It is certain that the method of detection proposed by the subcommittee will indicate any major insulation failure to ground, any failure between coils, any failure lengthwise of an entire group, and a streamer of appreciable magnitude. It would appear, therefore, that the problem of detecting insulation damage during surge testing has been solved in a manner satisfactory for all practical purposes.

In various conversations with operating engineers during the last 15 months, the writer has found several who were strongly opposed to impulse testing, fearing some damage to the insulation as a result of the test. But it was an interesting experience to see one operating engineer who was violently opposed to impulse testing, become one of its most ardent advocates. This change in attitude is, in a lesser degree, characteristic of the whole industry.

It was suggested last year that the subcommittee in undertaking this work should propose tests which would be relatively severe and not just some fireworks which might be fun to look at, but which wouldn't be significant. The tests which the subcommittee has recommended represent the consensus of opinion of the members in this matter of severity. They may or may not meet with general approval among the Institute members. While we desire to have a frank opinion from the members of the Institute regarding the recommended tests, it should be pointed out that we are working in a relatively new field. Our practical experience with commercial impulse testing is still limited. No field experience is now available on which to judge the adequacy of the proposed tests. But it would appear certain that the tests proposed would insure transformers of higher impulse strength than many now in service which have established excellent service records.

The writer would therefore bespeak a word of sympathy for the proposed outline of impulse tests and suggests that it be given a trial for a period of two or three years, at the end of which time we shall be in a much better position to know what changes should be made.

Mr. Vogel presents in his paper the fundamental data required to answer an important question which has occurred to all of us who have been studying the problem of insulation coordination: how much impulse strength can be obtained in a transformer designed to meet the existing A.I.E.E. low frequency tests? If we assume that the major insulation of the transformer is designed to meet this test with a proper margin, and if we assume further that the designer employs the necessary refinements (proper proportions, padding, elimination of creepage surfaces, shielding, etc.) to make the internal impulse strength, that is, between turns and coils, equal to that of the major insulation, how much impulse strength will be obtained in the transformer as a whole, and will this be sufficient to coordinate properly with present recommended gaps? Mr. Vogel's data indicate that in the higher voltage classes and down to the 34.5-kv class, internal coordination will be obtained both for long waves and for waves as short as 2 $\mu$sec, where the margin between the impulse strength of the insulation and the flashover voltage of the coordinating gap appears to be a minimum. This also will be true for both positive and negative waves. At the critical point of 2 microseconds, the margin of protection substantially is the same as that of the ultimate low frequency dielectric strength of the major insulation and the standard A.I.E.E. low frequency test voltage.

Below the 34.5-kv class, Mr. Vogel's data indicate again the necessity of raising the present standard A.I.E.E. tests and suggest values which would make them consistent with the recommended coordinating gaps. Mr. Vogel's paper makes a valuable contribution to the subject. He discloses for the first time the shape of the time lag curve for major insulation of transformers, its impulse ratio, and the nature and effectiveness of the internal coordination which will be obtained with gaps of the conventional type. I am glad he has confined his paper to this single problem, which is the paramount transformer problem of interest to those engineers who are shaping the industry's recommendations in this matter of insulation coordination. Best of all, the paper establishes from fundamental data the reasonableness of the recommended coordinating gaps and constitutes the best possible argument for their acceptance by the industry as the normal level of surge strength for the various voltage classes.

The paper by Messrs. Montsinger, Lloyd and Clem contains much valuable information and presents the results of a large number of tests on the impulse flashover values of insulator strings and gaps under a variety of conditions. It is regretted that the laboratories of Mr. Montsinger's company and of the writer's company do not agree fully as yet on all of these test results.

The authors emphasize the care and precautions necessary in this test work and point to agreement between the Schenectady and Pittsfield laboratories to substantiate the correctness of their results. We also emphasize the care necessary in making measurements of this kind and point with equal pride to agreement of results between our Trafford laboratory and our high voltage laboratory at Sharon. These laboratories are manned by independent groups of men working with quite different apparatus, yet their results agree very closely. I suspect that the source of the difference between Westinghouse and General Electric results will be found not in a lack of care on the part of either, but more likely in some difference in the fundamental standards employed by the two groups and on which their measurements must in the final analysis depend.

In spite of our laboratory differences at the present moment, there is one thought which I would like to leave with the utility engineers who will be using the results in working out their coordination problems. This thought, with which I believe the authors of the paper will agree is that the laboratory work involved in securing the kind of data presented by the authors and which will be presented by my associate is really an enormous job, and it has been carried on by our two companies at considerable expense. I feel that these laboratory groups, therefore, have rendered and are rendering the industry a great service—one which should be appreciated—because after all, this fundamental work is absolutely necessary to the successful conquest of lightning disturbances; necessary to a still closer approach to the goal of perfect continuity of electric service. I hope, therefore, that the attitude of the utility engineers toward these laboratory groups may be one of patience until they can remove their differences. In presenting our results and methods of measurement thus openly, we hope that out of the discussion may come some clue as to the cause of our differences, which may be helpful in overcoming them.

The statement in the paper that the gap is considered as a device for setting a maximum to the voltage which may be applied to the station apparatus, may be misleading to those less familiar with the subject, because the gap does not actually do this at all, as the authors well know. What the gap does do is to chop the wave. If low enough in magnitude, the wave is chopped on the tail, so in this case the wave is limited in length, not in magnitude. If the surge is high enough, the gap chops it on the front—not at any particular maximum value, but to a value depending on the steepness of the front. This is the factual interpretation of the function limiting the maximum voltage which can reach the apparatus.

The statement that the gap is not a protective device because it offers no relief from repeated applications of surges up to its flashover value seems to me meaningless. To claim that the gap is not a protective device is justified only if it is admitted that the transformer is not fully protected by it—that the transformer needs additional protection against repeated surges over the gap or of less than its flashover value. We design our transformers so that they are amply protected by the gap alone if proper ground wire protection against direct strokes over the substation is provided.

In regard to protection against direct strokes, I believe it is too early to claim that a sphere gap would protect effectively. It will provide, as Mr. Vogel points out in his paper, greater margin between the transformer insulation strength and its flashover voltage for very short time lags than the ordinary gap. But the steepness of the wave front of a direct stroke is very great—no one knows how great—and with waves of extremely steep front, even the sphere gap has a pronounced time lag, so the degree of protection would be somewhat uncertain at best.

Last year at the convention I reported on a commercial test which we had made on a 42,000-kva, 220-kv transformer using a wave front of 11,000,000 volts per microsecond, which was the nearest thing to a direct stroke that we could produce in the laboratory. This wave front was three times as steep as any recorded in the field, but Mr. Fortescue stated at the time that he believed a direct stroke to the bushing would even be very much steeper than that. Very little is known about the flashovers of gaps and bushings or the insulation strength of windings when subjected to these extremely steep wave fronts. It appears doubtful that we shall ever depend on insulation coordination for protection against these extremely steep waves. The best protection against direct strokes is effective ground wire protection over the substation and out onto the line at least for a short distance. This kind of protection properly designed can be depended on fully.

In connection with the proper location of protective gaps, Mr. Bellaschi has made a suggestion to improve the protection against very steep surges, which is discussed in the following. When a gap flashes over due to a very steep front surge it chops it on the front and passes on to the transformer an impulse of very high voltage of very short duration. If the gap is located right at the transformer it will experience the full voltage of this impulse, but if the gap is located at some little distance from the transformer, this impulse in approaching the transformer will have both the steepness of its front and the magnitude of its crest appreciably reduced due to the capacity of the transformer and adjacent apparatus and structure, thus subjecting the insulation to a much less severe stress. This is a very practical method of sloping off the front and suggests that perhaps the best place for the gap is not right at the apparatus but at some little distance from it, particularly if there are ground wires over the substation to prevent direct strokes to the apparatus. Better still, two gaps might be used, one at the apparatus and one at some distance away.

The authors of the paper suggest a level of impulse strength for bushings 15 per cent above that of the protective gap. We are in agreement that the bushing level approximately should be of this order. If this level is accepted, the degree of protection afforded the winding by the bushing can appreciably be increased and internal coordination made more effective. It is important that the impulse flashover of bushings be standardized rather than the 60-cycle dry flashover values, which are of no significance from an operating standpoint. In view of these facts, the proposed standard for 60-cycle dry flashover values for bushings which was submitted to the Electrical Standards Committee a year and one-half ago, when less progress had been made on insulation coordination, should be recalled and revised to establish impulse flashover values in place of dry 60-cycle values. There is no *positive* assurance that the desirable impulse values can be obtained with the present proposed 60-cycle dry flashover values. But it is only the impulse values and the wet 60-cycle flashovers that are of importance from an operating standpoint, or for the purpose of establishing a standard.

This subject was discussed by the Electrical Machinery Committee and it was recommended that the Transformer Subcommittee initiate some action looking toward a modification of this proposed bushing standard to substitute surge voltage values in place of the dry 60-cycle flashover values.

**H. K. Sels:** Referring to the several papers dealing with the insulation coordination of power transformers, it apparently still is the practise to consider the strength of transformer insulation in terms of a rod coordinating gap although a great deal of progress has been made with voltage measurements. If it is necessary to continue expressing insulation strengths with gaps, it might infinitely be better to return to a sphere gap standard that more nearly approximates the insulation volt-time curve. To carry this a step further, if we can use spheres, why not voltage and time directly?

From an operating standpoint, the use of a coordinating gap for protective purposes in a station is undesirable on account of tripouts. In order to prevent tripouts, some kind of lightning arrester equipment is necessary. Below are tabulated the voltages permitted at the terminals of present day arresters with test waves expressed in terms of a rod coordinating gap at 12 microseconds as compared with the proposed coordinating gap for power transformers.

| Voltage class | Transformer coordinating gap, in. | Arrester crest voltage gap, in. |
|---|---|---|
| 13,800 | 4.25 | 2.6 |
| 23,000 | 6.25 | 4.7 |
| 34,500 | 9.25 | 7.3 |
| 46,000 | 12.25 | 10.5 |
| 69,000 | 18.75 | 17.0 |
| 92,000 | 25.0 | 23.0 |
| 115,000 | 31.5 | 29.5 |
| 138,000 | 38.25 | 36.0 |
| 161,000 | 44.5 | 42.0 |
| 196,000 | 54.5 | 51.0 |
| 230,000 | 64.0 | 60.25 |

Since the arrester crest voltage is practically flat with time and transformer insulation has a much flatter volt-time characteristic than the coordinating gap, the necessity of expressing all measurements directly in voltage is emphasized by the small protective margin indicated by gap spacing alone.

Also, remembering that the protective value given above for the arrester is at its terminals without any allowance for impedance drops in the arrester and equipment leads and ground resistance, if any, there is some question whether the insulations proposed are sufficiently high. This is further emphasized by the recent trends to higher line, bus and bushing insulations.

Early agreement should be reached in expressing insulation characteristics by cathode ray oscillograms so that proper insulation levels may be selected by joint insulation coordination committees.

**Philip Sporn:** The report by Messrs. Vogel and Montsinger is a step in advance to put the question of transformer insulation and the entire problem of insulation coordination on a more rational basis. It cannot, however, be pointed out too strongly that almost everything recommended should be taken as a tentative recommendation, and that in many cases there is no question but that ultimate practise, when it is finally developed, is bound to be considerably different from that recommended here. Further, there is a great deal that still remains to be done to put the technique of impulse testing of commercial transformers on a sound commercial basis. This is true, for example, with regard to recommendations that tests be confined to the positive wave. While this may give a more severe stress to the transformer insulation, it is quite likely that coordination based on positive waves only will be entirely misleading and give a very poor and possibly dangerous setup under certain operating conditions. Again, the authors have apparently elected to slur over the very important question of determining whether or not any damage short of breakdown occurs to any portions of the windings in the process of impulse testing. It is apparent that this is too important to be left to chance. All these things, however, will come with time.

The paper does offer a basis of getting started and getting together some data and information on a method of testing that would sufficiently be close among all the groups following it so the data taken at various points later can be analyzed and interpreted with a view of making recommendations based on much fuller information than any that is available at the present time.

There are three points in Mr. Vogel's paper that are discussed in the following:

1. The statement that the average time lag curve of the major insulation of transformers is the same whether for positive or negative waves is not only not in agreement with the claims made by Messrs. Montsinger, Lloyd and Clem, but the data that Mr. Vogel furnishes are most certainly not conclusive or adequate to back up the claim. If the points presented in Fig. 9 give all the data, it certainly is far from conclusive as to variation of breakdown between plus or minus waves.

2. The claim, that coordination based upon present A.I.E.E. 60-cycle tests at operating voltages of 34.5 kv and above shows that the 60-cycle test requirements are satisfactory for coordination purposes, is contrary to experience cited before the Institute on several occasions, in which it was shown that equipment so insulated gave unsatisfactory operating results both with and without lightning arresters, and regardless of whether any coordinating gaps were present or not. It would seem as if great care ought to be taken in this regard before arriving at any definite conclusions.

3. A recommendation is made that a gap used should be protected by lightning arresters to obtain continuity of service. There is, of course, nothing new in this recommendation, this having been made many years ago. Here again, however, it ought to be pointed out that much data have been cited before the Institute in which attempts were made to prove the economic justification of lightning arresters, and that so far no data have been obtained that would justify it one way or the other.

Referring to Messrs. Montsinger, Lloyd and Clem's paper, the following points definitely call for comment:

1. The claim is made that nothing is gained by increasing the flashover of any part of the station equipment over that of any other part of the station. It would be very difficult for those familiar with the havoc wrought in a station or substation, upon occurrence of a short circuit of the bus itself, to agree with the authors. Further, if by the expenditure of a very modest sum, a short circuit can be kept away from the bus proper, then such an expenditure will be found economically worth while and will invariably be made.

2. It is stated that experience indicates that with modern arresters, gap flashovers are of rare occurrence. So far as I am aware, no such experience has been cited to the Institute or in any publication. It might be well for the authors to cite specific experience as a basis for their conclusions.

3. The claim is made that a cable itself is more or less a protective device. It would be interesting if the authors would furnish some information as to the length of cable necessary before the cable can really become a protective device, and whether in their opinion lengths of that order make it an economical protective device.

4. In Table V there is given a series of six different combinations of rod gaps, sphere gaps, lightning arresters, and capacitors for the protection against traveling waves. I would like to suggest to the authors a seventh combination in which no lightning arresters, capacitors, or gaps of any kind are employed, but in which a proper amount of insulation, possibly more than that required by A.I.E.E. standards, is used, where the only protective feature taken advantage of is the flashover characteristic of the bushing, that is, the protection the bushing gives the transformer as a protective gap. This particular combination has been employed a great many years and has worked very successfully and economically.

5. The recommendations with regard to gap spacing as a means of coordination have again the weakness in them pointed out several times before, and that is, since the insulation strength is a matter of volts and time, it might be well to coordinate in those terms. There does not appear to be any real reason why a primary unit like a volt should be shied at. A great deal of clarification of the entire problem ought to result if insulation strengths for any voltage are expressed in volts. The advantages claimed for the gap, based upon the fact that it will simplify the problem of coordination among the manufacturers, until such time as the various laboratories can iron out their differences, will disappear if the laboratories will agree upon and follow the recommendations with regard to insulation testing made by the Lightning and Insulator Subcommittee. Representatives of at least 4 laboratories have agreed that the procedure recommended is very practical and can be followed with advantage by all.

**F. J. Vogel:** In the paper by Messrs. Montsinger, Lloyd and Clem, there are many points of interest, and it is desired to emphasize some of those of greatest practical importance.

It is interesting to see that the authors have found that solid insulations have similar volt-time characteristics as the combination of fullerboard and oil ducts which they tested. I have found this likewise to be true except for the impulse ratio. As an example of this, I would cite the case of varnished cambric tape, as in cable insulation. For such a condition, a certain thickness has a one-minute strength of 100 kv, rms, or 141-kv crest. Its minimum surge strength is 230 kv, giving an impulse ratio of 1.63. This fact that different solid materials have quite different dielectric strengths is another reason why surge tests are essential to prove that transformers have the surge strength required regardless of their 60-cycle strength.

In Fig. 2, we find that the sphere gap has appreciable time lag characteristics, and we are glad that the authors have not only been able to determine that it exists, as we have previously, but to measure it and provide an accurate time lag curve. It is presumed that the voltage measurements were made quantitatively by sphere gap, since that is the Pittsfield standard of measurement. However, if the standard sphere gap also has a time lag, how can one be sure as to the accuracy of the measurements? If a divider is relied upon, I can well appreciate the care necessary to measure the time and voltage at such short lags, as a divider to serve this purpose must have a very high degree of fidelity. It is a pleasure, nevertheless, to see the authors' agreement with data taken by my associates in so far as the general shape of the curve for insulation in oil is concerned. However, it is to be noted that the data have been obtained from a single type of barrier not representative of high voltage transformer construction, and upon a relatively thin one. It appears therefore to me a bit rash to draw conclusions as to the relative positions at very short time lags of the various elements for all constructions and voltage classes. It similarly appears rash from a single series of tests and possibly random values on a few sample coil stacks to arrive at an impulse factor of 2.35. In other tests, values that high have been found, but to be conservative, the lowest values should be given the most weight.

Fig. 3 shows a generalized curve, but caution should be used in its application inasmuch as these relationships are different for the different voltage classes. Nevertheless, we agree that extremely high, short surge tests are most severe, as was brought out in Mr. Putman's paper[2] at the winter convention in 1932. At that time Mr. Palueff thought this not very severe due to the extremely short duration of the surge.

---

[2] *Surge-Proof Transformers*, by H. V. Putman, A.I.E.E. Trans., Sept 1932, p. 579.

There is a limit for the short-time protection of any transformer, and therefore perfect coordination for direct strokes of lightning is perhaps not possible. Mathematically, from the shape of the curves, for shorter and shorter time lags, the impulse ratios of all elements approach infinity, and infinity over infinity is rather an indeterminate ratio to use to determine a factor of safety. In simple language, this means that ground wire protection should be provided over stations and adjacent lines to furnish protection from direct strokes if they are feared.

The point has been missed in discussing the use of sphere gap characteristics for protection, that the lightning arrester is a factor. The best combination is a protective gap which is just protected by the arrester. At least for autovalve arresters, the plain sphere gap is the best arrangement without the addition of point gaps. Suitable characteristics are obtained from the Torok tube, multiple spheres in series and other electrode arrangements, so that either the added protection or a further degree of economy could be obtained if any station designer saw fit to require it. From Table IV, it is seen that the ordinary sphere gap is rather impractical due to its size.

From Table V, it might be inferred that the use of the sphere gap as a protective means made the transformer proof against direct stroke. I fear this is somewhat optimistic, since in the extremely short surge given to the transformer, described in Mr. Putman's paper of last year, simultaneous flashover of bushing, 64-inch gap and sphere gap set at 2,000,000 volts occurred. It seems to us to be a little uncertain that protection against direct strokes can be obtained on such meager data, even though it is fairly safe to gamble on due to the rarity of such an occurrence.

The terms "outdoor" and "indoor" seem less expressive than "exposed" and "unexposed" to lightning surges. It is true that much apparatus commonly inside substations has not been insulated up to the standard for outdoor apparatus, as it was not considered to be exposed to the surges entering from outside lines. I doubt if it is safe to set up levels for unexposed apparatus at this time, but it might be desirable to set up such limits for instrument transformers and the like.

In the paper the value of 4 inches is proposed for 13,800 volts instead of 4¼, as approved by the Transformer Subcommittee. Is this an error?

Referring to Fig. 4, the purpose of curve *D* is not clearly given. It is understood that curve *C* is proposed as a standard level for all bushings in the future. If this understanding is correct, this would seem to be in agreement with the proposal in my paper. In this paper, 10 per cent is given as a proposed value but it is realized that very close limits are difficult to obtain and the 15 per cent figure given seems reasonable. The author, however, does not state the purpose of the special bushings for power transformers.

It is believed that curve *D* is given for two purposes: first, to state a belief in the desirability of a larger factor of safety on large units, and second, to reflect past practise. The writer does not quite see the justification for curve *D* on the basis of an increased factor of safety for the power transformers, since smaller transformers may be connected to the same circuits, not to mention instrument transformers and rotating apparatus. Therefore it does not seem to us justifiable to maintain a higher factor of safety for any one class of apparatus.

Practises with different manufacturers with regard to the levels used in the past have varied, although it is not questioned that most power transformer bushings have been at a level approximately that of the special bushings for power transformers given. It should be noted that transformers coordinated with these bushings should have windings insulated in excess of the standard tests. It is our belief that it would be desirable to lower these values for future design except as specifically requested to the contrary for any given installation. If additional creepage surface is required on account of dirt or other operating conditions, it would be recommended that the bushings be gapped to the lower level.

It has been suggested that all bushings should be made oversize so that they can be gapped. By this procedure, the atmospheric corrections in surge testing can be taken care of by increasing the length of the test gap to suit, and bushings made to give the exact performance desired. It is not believed that this is a reasonable proposition, because of the following: first, atmospheric corrections can be made by correcting the surge voltage applied; second, it would result in an increase in size of the higher voltage bushings as well as the lower; third, many operators believe that bushing gaps are unsatisfactory.

**V. M. Montsinger:** Mr. Vogel's work confirms a claim which I have made during the past 5 or 6 years namely, that the 60-cycle strength of insulation (major insulation in a transformer) bears a definite relation to the impulse strength. In other words, the 60-cycle strength at any given point within a transformer winding is a rough measure of the impulse strength or *vice versa.* It should be kept in mind, however, that this definite relationship applies only to the major insulations; that is, to the insulations between two different windings or from a winding to ground, unless the impulse voltage distribution is kept uniform and in the same order of proportion from ground throughout the winding as the 60-cycle distribution. Thus in a winding which is perfectly shielded, the induced voltage test will equally well demonstrate its ability to withstand a given impulse voltage. For an unshielded winding the ratio of low frequency to impulse strength must be confined to the major insulation adjacent to the terminals.

The value of the impulse ratio of 2.2 checks quite closely the value of 2.35 given in our paper on "Coordination of Insulation." I have used 2.35 since 1927. Some of this difference of 7 per cent can be ascribed, no doubt, to the fact that Mr. Vogel's impulse kilovolt values are slightly lower than Pittsfield values. An easy rule to remember is that the major insulation impulse strength is 3.1 or 3.3 times the 60-cycle kv effective strength, depending on which impulse ratio value is used.

With reference to the statement in the paper that the insulation time-lag curve is nearest the point gap time-lag curve at 2 microseconds the results of my tests in Fig. 2 and Table III of the paper on *Coordination of Insulation* show that the insulation curve will cross the gap curve for short waves in the order of ¾ to 0.8 $\mu$sec and remain below for all shorter waves, assuming that the insulation strength is 10 per cent above the gap strength at approximately 2 $\mu$sec. Whether or not these curves cross is rather difficult to determine merely by comparing volt-time curves, due to the fact that the insulation test points are quite scattered—some points even indicating that the curves may not cross. The fact that they do cross, however, can definitely be demonstrated by making tests on insulation and a gap in parallel, which tests show that to give equal protection to the insulation the gap spacing must continually be decreased as the impulse front wave becomes steeper and steeper. This is well illustrated in Table III, which shows that while a 20.5-in. gap represents the impulse breakdown of a given insulation barrier for a full 1½-40 wave, a 10.5-in. gap represents the barrier strength when applying 3.5 times the minimum wave necessary to flash over the 20.5-in. gap. With 5 times the applied voltage and with a very steep front (zero resistance in series with generator) the equivalent gap was only 6.25 in. This seems to establish beyond any doubt the fact that unless there is a very large margin between the insulation strength and gap strength for the full wave flashover of the gap, the curves will cross for very short waves.

In connection with the proposal to increase the 60-cycle test on transformers of 23-kv rating and below I agree that these test values should be increased because practise has demanded more insulation than the test indicated. I do not agree, however, to the exact values that Mr. Vogel proposes because with a slight modification the test values can be expressed by a simple formula expressed in terms of the rated circuit voltage. Furthermore, the values derived in the same manner and based on Pittsfield impulse flashover of the proposed gaps are somewhat different being 20.3, 27.3, 35.7 and 51 kv instead of 21.6, 29.2, 37 and 48.5 kv as derived by Mr. Vogel. This question should be referred to the Transformer Subcommittee.

**Edward Beck:** This discussion pertains to the paper by Messrs. Montsinger, Lloyd and Clem.

The writer is in hearty agreement with the authors' remarks regarding the undesirability of more than one insulation level for apparatus in a station. The logical coordination is believed to be the establishment of a reliable coordinating level by means of lightning arresters or gaps located at several points if necessary. If the station insulation is then set at some level above this with adequate margin, coordination is secured. The pyramiding of insulations in a station operates against standardization, increases cost, and appears to be unwarranted if a reliable low level is established.

The coordinating gap is not a protective device as it usually is thought of, for its operation is closely allied to a flashover. Although the gap prevents flashover of insulation of greater strength than itself, nearby, its operation produces outages. The modern lightning arrester operates without these outages. In the laboratory a lightning arrester in parallel with a coordinating gap of the same voltage class protects it against flashover, and service experience has indicated that the probability of a gap operation in parallel with an arrester is remote. It is characteristic of valve arresters that they will attempt to drain as much surge current as is necessary to limit the voltage across the arrester terminals.

The authors recommend the use of gap combinations which will furnish a coordinating device with flatter impulse characteristics than those now recommended. We would point out that the modern valve type arrester possesses to a considerable degree these desirable characteristics and appears, therefore, a desirable medium for coordination. Discussions of insulation coordination should not leave the lightning arrester out of the picture. In order to obtain a flat gap the authors propose the use of rod gaps and sphere gaps in parallel or of combinations with capacitors. Why go to such complications? The sphere gaps must be protected from the weather if they are to maintain their characteristics. A gap of this type for a 138-kv class circuit for instance, would be no small matter, as will appear from Table IV of the paper. If gaps of flat characteristics are demanded in addition to the lightning arrester, it would appear to the writer more practical to use gaps of the type patented by Allcutt some years ago and used on Westinghouse electrolytic arresters, or other gaps designed to have flat characteristics which do not demand the space required by sphere gaps and are not subject to the damage which a sphere gap suffers when it flashes over. Experiments indicate that gaps with these characteristics can be built if they are found necessary.

The authors propose the use of gaps as measuring standards. It is the writer's opinion that this is not desirable. A behavior of gaps is dependent on numerous external factors which may vary from time to time and vary between laboratories. We believe that an attempt to use a gap as a standard will cause more complications than already exist in the coordination programs. The use of gaps in comparing the performance of devices whose characteristics are as radically different as the flashover of an insulator and the terminal voltage across a lightning arrester would be unsound.

It is our opinion that coordination should be based on kilovolt measured by means of the cathode ray oscillograph, which in the hands of competent operators is more reliable than measurements made by means of gaps that are likely to be affected by many factors difficult to control. The difficulties which had to be wrestled with in attempts to study the performance characteristics of lightning arresters before the DuFour cathode ray oscillograph was introduced into this country by Messrs. Goodwin and McEachron are easily recalled from memory. Let us not go backwards. If there is disagreement between laboratories, let these be ironed out rather than seek a temporary expedient in gaps.

**F. D. Fielder:** The paper by Messrs. Montsinger, Lloyd and Clem is discussed from a laboratory standpoint, since similar data have been secured at our Trafford Laboratory. It is noteworthy that much of the data are substantially in agreement, although there are certain cases where the discrepancies are large.

The determination of precise humidity correction factors for surge tests is difficult because of the many variables that must constantly be under control. At Trafford a room with special humidity control is employed for these tests. The majority of points are obtained at a constant temperature of about 100 deg F with an absolute humidity range from 2 to 15 grains per cubic foot; these are also checked at low humidities at normal room temperatures. These tests have indicated slightly different humidity correction factors for suspension insulators and air gaps, as indicated in the following table:

MINIMUM SURGE FLASHOVER VALUES: POSITIVE WAVES
Variation in per cent of the standard (6.5 grains) voltages

| Apparatus | 1-5 microsecond waves | 1.5-40 microsecond waves |
|---|---|---|
| Insulators | 1.0 % per grains/cu ft | 1.8 % per grains/cu ft |
| Standard gaps | 1.2 % per grains/cu ft | 2.4 % per grains/cu ft |
| Values from "Coordination of Insulation" | 1.25 % per grains/cu ft | 2.33 % per grains/cu ft |

The insulator values in the above table are averages from 1 to 10 grains per cubic foot, the usual testing range, in which the variation with humidity appears to be uniform. Although these differences are negligible compared to the present variation in some of the reported surge values, they might become appreciable in certain cases of close coordination. It seems evident that the data given in Figs. 7 and 9 are insufficient to warrant any but general approximations to the humidity correction factors. In Fig. 7, for the 0.5-5 microsecond waves at least, horizontal lines will fit the points fully as well as those shown. More complete and more significant data are required for the determination of correction factors.

The question is raised as to whether any check has been made on negative wave correction factors; since the flashover data in other curves of the paper are corrected to standard conditions, it appears that the same correction factors were used. A study of negative wave humidity correction factors has been scheduled at the Trafford Laboratory.

From Table VI of the paper, the conclusion is drawn that rain has little influence on surge values. This table is misleading and the conclusions are inaccurate because the water temperature for the test was so low. For the air gap the voltages average lower than for standard conditions, mainly because the absolute humidity was lower than standard. (Saturated air at 45 deg F is equivalent to 3.4 grains per cubic foot.) The other factor influencing the flashover value is the relative air density, which in the case given causes flashovers higher than normal because of the low temperature. If warmer water were used in these tests, approximating normal thunderstorm conditions more closely, it would be found that the air gap flashover values would increase fairly in line with the absolute humidity. Insulators, on the other hand, appear to have lower flashover values with rain, whether the water is cold or warm. It is these conflicting trends which occur simply as a result of normal rainfall that make coordination within close limits somewhat difficult. Fortunately the effects of humidity, and to a certain extent of relative air density, become less pronounced with either short time lags or with waves with short tails.

The authors of the paper have persistently recommended the use of the sphere gap for measuring impulse voltages, and have presented much data secured in this manner. It is not apparent, nor hardly possible, that their time lag curves as shown in Fig. 2 could be obtained in this manner. Rather, the time lag curve shown in Fig. 2 for a sphere gap offers convincing evidence against the use of sphere gaps for the measurement of surge voltages.

We do not recommend sphere gaps for measuring surge voltages, but instead the cathode ray oscillograph. In the first place, the sphere gap alone shows nothing but the crest value of the wave, while the oscillograph shows the whole: the rate of rise, the crest value, the rate of fall, and the time lag. In the second place, the sphere gap is misleading, often incorrect, unless used in conjunction with an oscillograph, for the wave shape is of great importance. Before satisfactory results are possible with sphere gaps, it is first necessary to secure and prove accuracy of the oscillograph and divider system for the waves used, for otherwise the actual wave shapes are unknown. Since the oscillograph must be proved accurate before sphere gaps are employed, its use might as well be continued. In the third place, many of the sphere gap calibration curves are calculated or taken from 60-cycle curves and have not been proved experimentally correct for surge tests. Before sphere gaps should be used for general surge measurements they should carefully be calibrated with surges by acceptable test methods.

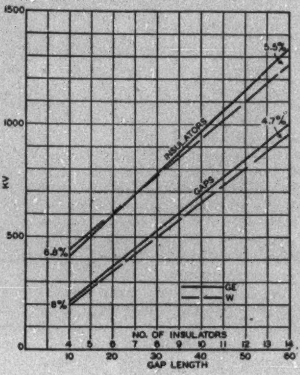

FIG. 1—COMPARISON LABORATORY RESULTS—1 ½/40 + WAVE

**A. C. Monteith:** The paper by Messrs. Montsinger, Lloyd and Clem accepts standards equivalent to those of the Lightning and Insulator Subcommittee for humidity; namely, 6.5 grains per cubic foot. The Westinghouse Company has been using this as standard in coordination work also, but some data recently obtained from the United States Weather Bureau indicate that previous to and during a storm absolute humidities as high as 9.5 grains have been recorded. Since the flashover of gaps, insulators, and bushings increase with humidity and transformer insulation is not affected by change in humidity it would appear from these data that the flashover should be considered at 9.5 grains for substation coordination work. The data obtained from the Weather Bureau also indicate minimum absolute humidities of 6.2 grains for eight storms tabulated. Where conservativeness in flashover values is desired, such as for line design, it is believed that 6.5 grains is a good value to use.

The authors have suggested the use of equivalent point gap spacings to express the impulse strength of various insulating structures, on the basis that this would eliminate corrections for humidity and air density and simplify the coordination problem. They have suggested an average gap spacing for the different waves to express insulator impulse strengths with a spread of 10 per cent in the lengths of gaps obtained. It is believed that this is complicated and for insulators, making use of average gap lengths, it is subject to differences of the same order of magnitude as actual kilovolt values obtained from different laboratories.

Test results on point gaps and insulators obtained from Westinghouse Laboratories as compared to the data presented by the authors, are shown in Fig. 1 for the 1½-40 wave and Fig. 2 for the ½-5 wave or 1-5 wave. It is seen that there is very close agreement with the 1½-40 wave while with the shorter wave, differences as great as 24 per cent exist. On insulators the differences are 11 to 17.8 per cent for the numbers of units shown. Equivalent gap lengths for expressing impulse strength of standard suspension insulators are shown in Fig. 3. It is seen that the spread in results from the two laboratories for gaps established at 6.5 grains is from 18.6 per cent to 10 per cent. The Westinghouse tests for humidity correction on medium and long gaps and insulator strings indicate that there is 0.6 per cent per grain higher correction for gaps than for insulators, in the range encountered in testing. If equivalent gaps are established in one laboratory at 1.5 grains and in the other at 6.5 grains (a possible range in testing conditions) an additional spread of 3 per cent would be introduced. These errors are as great as shown in Fig. 2.

Even using different gap lengths for different waves would introduce differences of larger magnitude than exist in kilovolt results based on the 1½-40 wave and differences at short string lengths approaching those of Fig. 2, for the 1/5 wave.

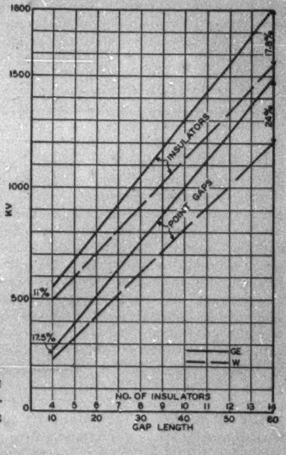

FIG. 2—COMPARISON LABORATORY RESULTS 1½/5 + WAVE

When all insulating structures used in a substation design, together with protective equipment are considered, the coordination becomes more complicated and more so if equivalent gaps are used. Fig. 4 shows relative volt-time curves for different types of apparatus in the substation. It is evident from an inspection of the gap curve compared to the others that when 10 per cent steps are considered for coordination purposes that an average gap could only be used for insulators. The complete picture for each piece of equipment would only be given by a gap length for each wave or time lag. If, as suggested by the authors, a voltage curve were established at the present time for the coordinating gap, the curves of Figs. 1 and 2 would be given by the two laboratories considered, with differences as high as 24 per cent. The only way the station designers could coordinate the various insulating and protective devices from different manufacturers would be to use a consistent base curve. The curve from either laboratory could be correct but the flashover level might be misleading if the wrong one were selected. Even if a consistent base curve were used with a gap length for each wave, still differences of 15 per cent could exist on insulators and there is no reason to believe that the differences for other apparatus would be less. Tests would establish the last point but it would be expensive and a burden to the laboratories with already heavy schedules, the personnel of which is spending all its available time trying to reconcile fundamental differences in measurements.

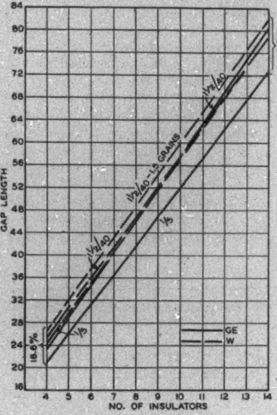

FIG. 3—SUSPENSION INSULATORS IN EQUIVALENT GAP LENGTH

It would appear better to recognize that there are laboratory differences, as has been done in the past, and until they can be eliminated compare the results from the different laboratories, put in a correction to put them on a common basis and coordinate with kilovolt values which the authors agree is the most desirable and fundamental. This still would be subject to the criticism of not knowing definitely what the flashover level was but it would allow using a yardstick which was a familiar engineering measurement. It would eliminate inaccuracies of different gap lengths from manufacturers for the same equipment on the same wave.

It is believed therefore that better results would be obtained by using corrections in kilovolt values. Gaps, it is believed, would complicate a subject already becoming involved and would result in differences due to varying test conditions.

**K. B. McEachron:** The writer pointed out in a discussion[3] of the paper by Montsinger and Dann, presented at the summer convention in 1930, that the use of a single gap was the best method of establishing a level of insulation, because such a gap could be protected by a lightning arrester near by, thus preventing interruptions to service. It was also pointed out that such a gap should be welcomed by the manufacturers and users of lightning arresters, as it gave a measure of both the arresters' performance and the strength of the transformer in service.

Subsequent experience has borne out the position taken in 1930 and today the principle of coordination is laid down along the lines above indicated. However, the problem does not appear today to be completely solved by the use of the simple rod or point gap as a coordination gap. It is shown in the Montsinger, Lloyd and Clem paper that insulation as used in the transformer does not exhibit the degree of time lag in its breakdown which is shown by oil or air. Thus it is not permissible to protect such insulation by a lightning arrester which has high time lag in its breakdown, if steep waves as from direct strokes are to be allowed to reach the installation. This illustrates one of the important advantages of the thyrite station arrester whose compensated gap has a flat breakdown characteristic.

In establishing the coordination gap it is desirable to use a gap having volt-time characteristics parallel with the insulation failure curve. The paper explains how this may be done, approximately by the use of the sphere gap in parallel with the rod gap. Although the setting of the rod gap, used alone, can be decreased until the proper ratio to transformer strength is secured for the steepest waves as with direct strokes, yet such a method reduces the 60-cycle and slow impulse flashover in like proportion which reduces the margin between the arrester and the gap unnecessarily. Since by far the great majority of disturbances reaching the arrester are not direct strokes close to the station, any unnecessary reduction of margin between the arrester and the gap should be avoided.

It is important to make clear that the volt-time characteristic of the arrester and the insulation should substantially be parallel at all wave fronts. The coordination gap should have a volt-time characteristic parallel to that of the insulation thus retaining the highest practical value for slow waves. With such a coordination the arrester will always protect the gap and the gap will always bear a correct relation to the strength of the transformer. Thus the transformer is protected and outages avoided.

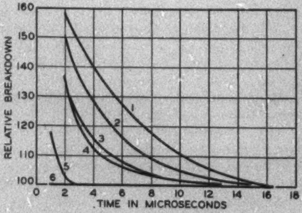
Arresters are not designed to withstand direct strokes of the greatest possible magnitude, but they will perform properly at currents which correspond to the weaker direct strokes. The use of a gap having the matched characteristic mentioned before would act to make the combination of arrester and gap safe for all kinds of direct strokes, although an outage might occur if the gap should function.

With extremely steep waves short distances may account for considerable voltages which is a fact requiring consideration. If 5,000 kv per microsecond is taken as typical of severe direct strokes then a potential of 5 kv per foot of conductor will be found, which may be doubled if reflections can occur. Thus if a gap is set for a potential of 500 kv less than the flashover of a bushing a distance of only 100 ft would be required to allow flashover of the bushing. This distance would be reduced to but 50 ft if a reflection to double potential took place.

FIG. 4—COMPARATIVE SHAPES—VOLT-TIME CURVES

1. Bushing
2. Pillar insulator
3. Point gap
4. Standard suspension insulator
5. Major transmission insulator
6. Crest autovalve arrester

100 per cent = 760 kv



It is not difficult to see, therefore, that large stations covering considerable territory cannot properly be coordinated with respect to direct strokes unless the gaps are relatively close to the transformers and the arresters must also be close by. It is better in case considerable distances are involved to keep the direct strokes off the station by overhead shielding conductors. If the overhead ground wires are extended out from the station so that the incoming front is sloped the potential per foot of conductor is decreased and distance between the transformer and the protective equipment becomes of less importance.

---

[3] A.I.E.E. TRANS., Vol. 49, Oct. 1930, p. 1506.

The following is a discussion of the paper by Messrs. Rudge, Wieseman and Lewis:

It has been proposed that lightning arresters or their equivalent might be used between the neutral of the Y-connected generator and ground for preventing reflections at the neutral. If reflections at the neutral could be prevented, arresters at the terminals of the machine could, according to the paper, hold the voltage to a value of $2.12E$ and protect the major insulation successfully. To do this, however, requires that there be no positive reflection at the neutral. This means that the neutral must either be grounded through a resistance equal or less than the combined surge impedance of the windings discharging into the neutral ground resistance or it must be a capacitor of sufficient capacitance to prevent its being charged to a potential equal to the strength of the winding for any length wave which the generator may receive from its connected circuits.

On account of telephone interference the use of capacitance in the neutral does not appear to be a satisfactory solution to this problem. Because of the fact that during a fault in which one phase may be grounded it is necessary that a neutral resistor, if used, have sufficient current carrying capacity to prevent its failure during the time such a fault may exist. On account of circulating current and for other reasons it usually is undesirable to ground more than one generator in a station even if grounded through a resistance equal to the surge impedance of the windings of the machine.

On account of the possibility of faults occurring on one phase and also to avoid the operation of the generator with neutrals continuously grounded, the use of a material like thyrite has been suggested as a neutral resistor. However, any material having characteristics like thyrite is not suitable, for the following reason:

The dimensions of the thyrite would be so arranged as to provide a resistance equal to the surge impedance when the current flowing to ground was equal to the traveling wave currents expected through the machine. For all other currents less than this the resistance would be greater than the surge impedance of the machine and a positive reflection would take place. A lightning arrester connected in the neutral would perform in a similar manner in that up to the time that the arrester began to function a positive reflection would take place, which when reflected back through the windings toward the terminals of the machine would superimpose on the increasing voltage of the tail of the wave so that the potential somewhere between the line terminal and the neutral would exceed the strength of the machine.

This is well illustrated by an example; assuming that the terminal arrester holds the voltage to $2.12E$ and that the neutral arrester is so designed that it holds the voltage to $E$, a wave entering the machine having a front sloped as required to prevent turn stresses would have its crest voltage limited to $2.12E$. When the beginning of the wave reached the neutral arrester it would reflect just as though no arrester were present until a voltage of $\frac{1}{2}E$ in the traveling wave had been reached, which would be sufficient to cause the arrester to go into operation. If the arrester's resistance were less than the surge impedance no further reflection in the positive direction would take place. However, the original wave up to $\frac{1}{2}E$ allowed by the arrester would travel back through the windings of the machine and add to the incoming wave of $2.12E$, allowing a value of $2.62E$ to be impressed on the major insulation of the machine. This would stress the machine beyond its strength.

Calculations indicate that any device connected in the neutral which is connected into circuit through the operation of a gap would impose severe turn stresses on the machine at the neutral because of the sudden decrease in potential when such a gap sparked over.

The best method, therefore, of preventing reflections at the neutral in the light of present knowledge appears to be the use of a capacitor connected at the terminal of the machine having sufficient capacitance so that the wave is sloped sufficiently to prevent the application of voltages higher than the machine strength as the result of neutral reflection.

**E. D. Treanor:** The papers by Messrs. Montsinger, Clem and Lloyd, and Mr. Vogel present much more fully than has hitherto been done the behavior of insulation and rod gaps with reference to waves of different shapes and magnitudes. Messrs. Montsinger, Clem and Lloyd's paper particularly shows the unfortunate characteristics of simple rod gaps in the short-time range for use as measuring or coordinating devices. The great advantages of the rod gap for such purposes are its simplicity and ease of duplication, and these advantages may make it difficult to improve on the rod gap for these purposes.

However, the failure of the rod gap characteristic curve to parallel the corresponding insulation breakdown curve raises the question as to whether the Transformer Subcommittee's tentative recommendations for impulse testing require modification by the addition of a test wave of steeper front than the 1½-40 wave already suggested, or if only one wave is desirable, whether it should be of a very steep front or be a compromise between the proposed standard and a wave in the region of very short fronts.

This difficulty of making choice of one or more test waves which would satisfactorily demonstrate the strength of the transformer would largely be obviated by the use of a gap with approximately level characteristics, such as the combination of rod and sphere gaps described by Messrs. Montsinger, Clem and Lloyd. This is only one form of gap with such characteristics. Others are, at least, theoretically available. With such a gap, the problem so far as testing goes is very much simplified. Any convenient wave in the range that has been explored would be satisfactory and its standardization could be based on convenience to produce, ease and certainty of measurement, etc. The effect on the internal insulation of transformers of steeper wave fronts would have to be considered, but so far as the major insulation is concerned, the variation in magnitude of total stress will be much reduced.

Of even greater importance would be such characteristics in gaps used as coordinating devices to insure that a proper margin would be maintained in service between apparatus of a given strength and waves which can reach the apparatus over the lines. While a number of waves having fronts of an order to make rod gaps with recommended settings ineffective and maintaining this satisfactory margin may be, and probably is, very small, the question of reducing rod gap settings so that they will provide a proper margin against waves of the order of direct strokes has already been raised. While it may be some time before we have precise knowledge of the characteristics of direct strokes, there are some indications that the rate of rise may not be very much more severe than the waves now capable of production in the laboratory.

If a simple rod gap be reduced in setting far enough to leave a margin against even these steepest artificial waves, its use would be hampered by the resulting numerous flashovers from long waves of slow front and low magnitude or even switching surges.

Such use of rod gaps with low settings has been suggested. A gap with flat characteristics under similar conditions would determine coordination under practically all waves and facilitate the use of arresters having similar flat characteristics.

**J. K. Hodnette:** Messrs. Harding and Sprague have presented data based on laboratory tests to support the conclusion that the interconnection of lightning arrester and distribution service grounds results in improved protection of distribution transformers from lightning over the standard method of connecting the arresters between the primary leads and earth. This subject was discussed at length at the 1932 winter convention and has now generally been accepted. It limits the surge voltage between the primary terminals and the secondary neutral which for modern transformers is much less than the insulation strength of the windings.

The interconnection, however, cannot be made universally but is limited in its application. The surge current is discharged through the neutral service grounds, so that the interconnection cannot be made where the neutral is not grounded. It is not applicable to three-phase installations having delta-connected secondaries for supplying three-phase or motor loads for to do so would subject the connected apparatus to excessive surge voltages.

Where the transformer tank and core remain at some intermediate potential between that of the primary and secondary windings during the discharge of the surge current the transformers will be protected, although the potential of both the primary and secondary winding may rise to a high value above ground. However, if the tank is free to acquire some different potential, particularly in the case of an accidental ground maintaining the tank at or near ground potential, the difference in potential may become excessive and a flashover of one of the windings result. The same is true for transformers mounted on metal or conducting poles unless precautions are taken to connect the tank and the arrester and service grounds together. Therefore, in order to insure complete protection, it is necessary to take the tank into consideration and properly to coordinate or limit the potential between the tank and windings.

The interconnection between the lightning arrester and secondary service grounds should be limited to cases where there is a number of dependable service grounds of low resistance connected in parallel. It is not recommended where the ground resistances are high. This is emphasized by the fact that past experience has indicated that lightning arresters occasionally become leaky or short circuit, and if such arresters are interconnected with the secondary service grounds, primary current will flow to ground over the secondary service conductors. If the ground resistance is not low to start with, it may materially be increased through the drying out effect of the leakage current with the result that primary potential will be impressed on the secondary service lines for a considerable period of time or until the circuit is interrupted. In case the arrester is connected on the line side of the transformer fuse, the current will continue to flow until the feeder breaker is opened.

As a safety measure the lightning arrester should always be connected between the fuse and the transformer where the interconnection is used.

The flow of dynamic leakage current can be prevented by interposing a gap insulated for primary voltage between the lightning arrester ground connector and the secondary neutral, and without affecting the efficiency of the protection against lightning.

**A. M. Opsahl:** The writer believes that Messrs. Harding and Sprague have been mislead in one of their conclusions. They state that the voltage on the primary neutral as illustrated in Fig. 9B is due to a failure in the primary winding. This is not necessarily true. There is no discontinuity in the voltage wave to show a spark in such a failure. The voltage impressed on the primary phase wire is represented in Fig. 4. This surge after being transmitted through the primary winding to the primary neutral would have the modified shape shown in Fig. 7 with the somewhat higher voltage due to reflection. These values are determined by the effective transformer primary reactance and capacitance. The authors do not state the kva ratings of the transformers used. If a load such as the neutral line wire, or an equivalent 250 or 500 ohms to ground were connected to $H_2$ the voltage from $H_2$ to ground would be greatly modified. A secondary load will have an effect in decreasing the effective primary reactance.

**C. L. Fortescue:** The following is a discussion of the paper by Messrs. Harding and Sprague:

The results of the lightning investigations carried out by two of the leading manufacturers jointly with some of the electrical utilities during the past five or six years has given the electrical industry a vast amount of data on lightning and surges on transmission and distribution lines due to lightning. The technical analysis of these data has reached a state of development such that the performance of high-voltage transmission lines when subjected to direct strokes of lightning can be predicted with a reasonable degree of accuracy. New transmission lines designed and constructed according to principles deduced from the analysis of these data have been built and their performance has more than come up to the expectation of their promoters. The overhead ground-wire protection for the line has been extended to substations and with the advances made in the art as a result of these investigations, for a well protected high-voltage system, the likelihood of surges of extreme steepness and crest value entering the substation has been reduced to a negligible quantity. Practically such high surges as occur will arise from direct strokes in close proximity to the station, and then only in the remote possibility with proper coordination will failure of the overhead ground wire protection of the station result.

While not economically justified except for transmission voltages of 220 kv and above, it appears to be technically feasible to build a line that is lightning proof. Our engineers have assisted in the design of lines which have been in service in severe lightning territory for several years without a single outage.

The development of surge testing apparatus and the technique of surge testing has kept up fully with the increase of knowledge of lightning phenomena, and while the several large lightning laboratories which have been cooperating to secure reliable data on impulse strength of bushings, pillars, coordinating gaps, etc., have not been able to reach perfect agreement for short time lags it is expected that it will not be long before they do.

The increased knowledge of lightning phenomena on transmission lines and development of the technique of surge testing, have proved definitely that the danger to electrical apparatus insulation does not arise from the surges of normal operation nor from overvoltages of normal frequency which last for considerable time, but are due entirely to lightning surges, most of which last only a few microseconds. Therefore, surge testing of electrical apparatus is indicated as the logical procedure to determine those suitable for service. The question of test procedure and proper test values to determine whether all parts of the apparatus are coordinated properly is in the hands of the different subcommittees of the Apparatus Committee of the A.I.E.E. and also of the joint NEMA-NELA Committee on Coordination of Insulation.

The discrepancies which Professor Harding mentions in his paper between the coordination characteristics of different makes of surge-proof transformers will in the course of time undoubtedly be ironed out. Manufacturers of electrical equipment will be compelled to provide themselves with surge testing equipment or run the risk of losing out in competition with those who are equipped, for it is practically impossible to carry out the research and development necessary to produce properly coordinated insulation in electrical apparatus without the use of such equipment. Several manufacturers of electrical equipment have taken advantage of the fact that we have developed such equipment to a high state of perfection and have purchased outfits from us. One large utility has purchased one and we expect more to follow. The policy of the company with which the writer is associated is to encourage the carrying out of surge testing by utility engineers, for the more of this that is done, the sooner will the manufacturers appreciate the requirements that their apparatus must fulfill and the sooner will competition be placed on a sound basis.

While we do not have any standard surge test our practise in testing surge-proof distribution transformers is to carry out the surge-test with normal 60-cycle voltage on the transformer. Our surge-proof distribution transformer has been subjected to repeated tests of extreme severity under these conditions representing a great many years operating service, without the slighest sign of weakening of the insulation. Surges have been applied up to 1,500,000 volts without any damage to the insulation.

Table I in the writer's opinion does not mean very much, it only indicates the value of the surge that the arresters or protective device permit across the various parts of the transformer. Distribution type arresters have become well standardized and this is indicated in Table I, transformers 1, 2, 3, 4, 5 and 7. In No. 6 the impulse flashover of the protective device used is higher than for the distribution arrester, but the surge potential permitted by the protective device may be well within the safety limit of the insulation.

We have known for some time that there is a great variation in the bushing flashover of different makes of transformers. It is desirable to provide a bushing with fairly high flashover but the impulse strength of the bushing should be coordinated with that of the insulation, so that in an unprotected transformer bushing flashover will take place outside the case, protecting the internal insulation from failure. In Table II transformers *A*, *B*, *C*, and *D* were not properly coordinated, otherwise insulation puncture would not have taken place.

**D. W. Roper:** In a discussion in 1927 with engineers of the Electric Service Supplies, General Electric, and Westinghouse Electric and Manufacturing Companies, it was recommended that the Commonwealth Edison Company make a trial installation of interconnecting the ground wires of lightning arresters and the grounded neutral main of the secondaries of the 4-kv overhead distribution system. Subsequently, in order to determine what the effects of such an interconnection would be on the voltages on the customer's wiring at the time of lightning discharges, arrangements were made by the Utilities Research Commission to have tests conducted at Purdue University. The test results indicated that there was no hazard created on the customer's premises by the interconnection; and the interconnection was recommended in a paper[4] of a year ago by Messrs. Harding and Sprague and also in their present paper.

In order to check the effect of the interconnection the Commonwealth Edison Company installed 3,000 interconnections early in 1932 in blocks where the overhead gangs had other work, so that the locations were scattered well over the city. As only one lightning arrester per phase wire is installed in each block, the number of transformers affected was about 5,700, or about 17 per cent of the total.

The records for the year 1932 indicate that a reduction of over 60 per cent in transformer troubles (fuses blown and transformers burned out) due to lightning is secured by this interconnection. The records also indicate that in the average year, the total number of transformer troubles due to lightning in Chicago will be less than 5 per one-thousand transformers per year.

It happens, however, that this interconnection is prohibited by the National Electrical Safety Code and by the rules of the Illinois Commerce Commission. Permission was obtained from the Commission to make these interconnections with the proviso that they would be made only at those locations where, in addition to two driven grounds on the secondary neutral wire, the neutral wires of two services were grounded to water pipes on the premises of customers, and with the further proviso that we were to report all adverse incidents in connection with these installations. No such adverse incidents due to this interconnection have been noted to date.

As recorded in the *Electrical World* for December 24, 1932, Messrs. Haines and Corney reported a considerable reduction in lightning troubles on a similar trial installation of 777 transformers without a single case of trouble with the customers' wiring or meters.

In view of this favorable report on two field trials of the interconnection between the lightning arrester ground wire and the grounded secondary neutral wire, and in view of the recommendations for the interconnection, it is recommended that the Institute use its good offices to secure such changes in the National Electrical Safety Code as will permit this interconnection under proper safeguards.

**L. V. Bewley:** Messrs. Rudge, Weiseman and Lewis propose a protective layout consisting of four principal elements:

1. An overhead ground wire extending out from the station for 2,000 ft or more, and intended as major defense against direct strokes occurring within that distance of the station.
2. Line type arresters at 2,000 ft, and perhaps also at 500 ft from the station, to limit the crest of surges having their origin beyond the ground wire section.
3. Station arrester to limit the voltage applied to the machine winding (in the case of effectively grounded neutral machine).
4. Terminal capacitors to retard the wave front entering the winding so as to keep the gradients within safe limits; and to limit the crest of waves entering isolated neutral windings.

Wave as Reduced by Intermediate L.A.

Fig. 5

Theoretically, with an ideal ground wire having zero grounding resistance, there is no excuse for either the station arrester or the intermediate line-type arrester. Actually, however, since the ground wire is some 0.2 microsecond from ground, and the grounding resistance can not always be reduced to the extremely low value required, excessive voltages may reach the machine terminals, and therefore station protection is necessary. Referring to Fig. 5 of this discussion, suppose that a lightning stroke has hit the ground wire. Then a wave starts out on the ground wire, and induces an accompanying wave of the same shape and about a quarter the amplitude on the line wire. Now for a high voltage stroke rising at a fast rate (say 10,000 kv per $\mu$sec), the sparkover voltage of the insulator will be reached before waves of reduction can return from the tower footing, and thus a sparkover is inevitable. At the instant of sparkover the waves on the ground and line wires become equal at a value somewhat lower than the crest of the wave on the ground wire just preceding sparkover. This decrease is due to the reduction of surge impedance. A little later the reflections return from the tower footing and reduce the advancing wave crests on both line and ground wires to a value

$$E = RI$$

---

[4] *Interconnection of Primary Lightning Arrester*, A.I.E.E. Trans., March 1932, p. 1234.

where $R$ is the tower footing resistance and $I$ is the tower current. The reduction continues, on account of reflections from adjacent towers, until finally the wave on the ground wire vanishes; but the wave on the line wire moves on and develops a total length equal to the time that it takes the reflections to reduce the voltage at the stricken tower to a negligible value. This may take several microseconds, and in the meantime there impinges on the machine terminal a wave of that length and sustained crest $E = RI$. For example, if $I = 100{,}000$ amperes and $R = 2$ ohms, the incident wave would be 200 kv and would prove destructive unless limited by the capacitor or station arrester. Now there is little hope of keeping $R$ down to such a low value, and so it is seen that either a station arrester with a small capacitor or a capacitor sufficiently large to absorb the voltage slug of length $2T_2$ is a quite necessary part of the protective scheme. Had a perfect ground been instantaneously available at the instant that the lightning struck, no wave could have propagated on the line wire. If the intermediate arrester is between the stroke and the machine, it will greatly reduce the wave on the line wire, and to that extent relieve the station protection.

In the appendix to the paper there are given the equations for the first five entering waves, from which the line terminal and neutral voltages, for either grounded or isolated neutral, can easily be computed. An alternative expression for the $n$th entering wave and for any neutral resistor is given by—

$$V_{ne} = \frac{2E\,(-a)^{n-1}}{Z_1C}\;\frac{(p+G)^{n-1}}{(p+A)^n}\;\epsilon^{-Bt}$$

$$= E\,(-aS)^{n-1}\frac{K}{M}\left\{(\epsilon^{-Bt} - \epsilon^{-At}) + \epsilon^{-At}\sum_{k=1}^{n-1}\left[-\frac{(2t/K)^{n-k}}{\underline{\vert n-k}} + \frac{S^{-k}\,\underline{\vert n-1}}{k\,\underline{\vert n-1-k}}\sum_{r=1}^{k}\frac{(-1)^{k-r}\,(2t/K)^{n-r}}{\underline{\vert k-r}\;\underline{\vert n-r}\;\underline{\vert r-1}}\right]\right\}$$

Where

$$a = \frac{R - Z_2}{R + Z_2} = \text{reflection factor for neutral}$$

$R$ = neutral resistor

$G = (Z_2 - Z_1)/Z_1Z_2C$

Other notation same as in paper.

**Robert Treat:** It is not many years since the orthodox answer to the question "How can I best prevent lightning damage to rotating machinery which is connected directly to overhead lines?" was "By the interposition of a one-to-one transformer between the two." The paper by Messrs. Rudge, Wieseman and Lewis indicates that considerable progress has been made since those days. We no longer feel that an insulating transformer is the best lightning protection; nor do we feel that a transformer constitutes the 100 per cent protection that we used to believe it did.

The problem of protecting rotating machine insulation is more difficult than that of protecting the insulation of transformers and other stationary apparatus because of the lesser margin between normal operating voltage and breakdown strength. Because of this the difficulty of securing a satisfactory degree of protection is somewhat greater than in the case of stationary apparatus; on the other hand, the need for protection is also that much greater.

In an art as old as that of protecting transformers from lightning damage the doctors are not yet entirely unanimous as to the exact place in the picture to be assigned to the lightning arrester. In an art as new as the one covered in the present paper, it is not to be expected that the final word will have been said for some time to come.

It is the writer's firm conviction that an intelligent application of the protective means suggested in this paper will generally reduce the probability of machine failure by an amount sufficient to entitle the protective equipment to be regarded as very cheap insurance. At the same time, considering the newness of the art and the probability of further progress being made in the next few years, it should not reasonably be expected that 100 per cent protection can now be provided under all conditions. One should not be too disappointed, therefore, if he still experiences an occasional failure after the installation of protective equipment; particularly if the protected apparatus has been operating for a period without protection and possibly has already suffered some incipient damage.

**J. F. Calvert:** There are several approximate circuits for the generator winding, each of which has its limitations as well as its applications in surge studies. Messrs. Rudge, Wieseman and Lewis have made use of the assumption put forward by Mr. Boehne, that the armature winding may be treated as a transmission line or cable, but one which permits a very low velocity surge to propagate along it. This scheme will give moderately accurate data on the voltages at the ends of the windings and, in the case of the delta-connected machine, at the midpoint of a phase as well. It is not at all accurate for other points in the winding. It seems to give a reasonably accurate means of calculating the natural period of the machine, though a large number of machines must be tested and calculated to prove this, so that the effect of slot shape and number of conductors per slot could be allowed to enter. It gives a value of voltage between turns at the line end which is too high because of the voltage induced in the adjacent turns by magnetic and electrostatic coupling.

Accurate data on surge penetration into armature windings must as yet depend largely on test data rather than on theoretical analysis. It is unfortunate that no test points have been shown with the test curves of this paper. The writer believes the authors should state for each curve how many machines were tested and what was the maximum variation of test data from the curve. Further, were these all multi-turn coil machines? Did they have similar slot proportions? How many turns per coil were there in the various cases? Was the rotor in or out of the stator?

It is believed that the assumption made by the authors concerning the protective method will result in optimistic rather than pessimistic results for the volts to ground in the machine. The scheme of charging the condenser through the surge impedance of the line is a compromise, for the use of a more lumped impedance with capacity and arresters at the terminals of the machine admittedly will give more complete protection.

It is noted that the authors have assumed a 0/40 wave on the machine side of the arrester, which is located 2,000 ft from the machine terminals. From published performance of arresters, it can be shown that in order to produce such a resultant arrester wave, a 0/18 wave would have to originate on the line. While it is probable that a large percentage of the lightning surges experienced at a particular location will not appreciably be longer than this, longer waves have been measured and may be experienced.

It is felt that a $O$ front flat-topped wave should be assumed as that which passes the arrester, because this is practically what passes an arrester when a severe surge originates on the line.

**E. M. Hunter:** In protecting rotating machines from damage by lightning voltages, consideration must be given not only to the crest but also the front of the voltage wave entering the machine winding so that the resulting voltage distribution in the winding will not damage the turn or neutral insulations. The lightning protection given transformers usually is inadequate for rotating machines because, as Messrs. Rudge, Wieseman and

Lewis have shown, the impulse strength of the insulation of rotating machines is relatively low compared with the impulse strength of the insulation of transformer, lines, etc., to which machines are connected and hence special protective equipment is necessary for this apparatus.

Suitably located special lightning arresters alone at or near the terminals of a machine do not give adequate protection because an arrester limits only the magnitude of the surge voltage to ground and exerts little or no influence on the front of the wave and hence it is necessary to supplement the protection obtained from the special arresters by equipment which will reduce the voltages appearing across the winding turns and at the neutral to values safe for the machine insulation.

In the protective schemes described by the authors, this supplementary protection is obtained by shunt capacitors to ground at the machine terminals. Inductance, located in series between the machine and transmission line also will slope off the front of the incoming voltage wave and a brief summary of what can be accomplished with inductance is given here.

Based on the single conductor theory of traveling waves, the equation of the voltage wave entering a machine caused by a 0-40 μsec voltage wave reaching the machine from over a transmission line through a series inductance is

$$e = \frac{2EZ_2}{Z_1 + Z_2 - 0.0173 \times 10^6 L}\left\{ \epsilon^{-0.0173 \times 10^6 t} - \epsilon^{-\frac{(Z_1 + Z_2)t}{L}} \right\} \qquad (1)$$

where

$Z_1$ = surge impedance of transmission line
$Z_2$ = surge impedance of machine
$E$ = crest of incoming voltage wave
$L$ = series inductance

which shows that with a 0/40 voltage wave arriving at the machine terminals, a voltage wave with a sloping front enters the machine.

The voltage appearing across the machine turn insulation and the reflected voltages at the neutral are dependent upon the slope of the incoming wave. The equation of the slope is obtained by differentiating equation (1), and from the slope, the voltage ($E_T$) across the turn insulation is

$$E_T = \frac{2EZ_2 t}{L} \qquad (2)$$

Mr. E. W. Boehne has shown that the average velocity of propagation of electric waves in machine windings[5] is approximately 10,500 miles per sec. Thus the time required for a wave to travel one turn of a coil is

$$t = 1.5\, D\, 10^{-9} \text{ sec}$$

where

$D$ = $(1.8\, d + 0.1\, mlt)$ = length of turn
$d$ = stacking length of armature core
$mlt$ = mean length of turn of coil

From equation (2) then, the formula for the series inductance to slope the incoming voltage wave is

$$L = \frac{3EZ_2 D\, 10^6}{E_T} \text{ henrys} \qquad (3)$$

where

$D$ = length of turn in inches
$E$ = crest of incoming wave in kilovolt
$E_T$ = maximum allowable voltage across turn insulation in volts
$Z_2$ = surge impedance of machine in ohms

Fig. 6D of the paper shows that a 0.5-μf capacitor at the terminals of a machine, in conjunction with suitable arresters, will prevent the neutral reflected voltages from rising to dangerous values. With the aid of equation (1), it can be shown that a 0.1 henry series inductance at the terminals of the machine will accomplish the same result. However, it would not be practical to use an inductance of this size as it would interfere with the normal transfer of power from a machine.

The authors have also stated that a 0.1-μf shunt capacitor at the terminals of the machine together with suitable arresters will slope off the front of the incoming voltage wave sufficiently so that the resulting voltage distribution in the machine winding will not damage the turn insulation. It can be shown by equation (3) that with the same arrangement of arresters as proposed by the authors, a 0.02 henry series inductance at the terminals of the machine should give the same turn protection for a machine with a surge impedance of 800 ohms. This is considerably more inductance than usually is found in current limiting reactors, induction voltage regulators, etc. However, this value of inductance is conservative, especially for machines with a low surge impedance, and hence a lower value of inductance may often give sufficient turn protection. When there is apparatus having inherent inductance in series between a machine and the transmission line, its protection value should be considered in selecting lightning protective equipment for the machine.

For machines directly connected to overhead lines, the protective schemes proposed by the authors depend upon a definite voltage level being established in an adjacent region of approximately 2,000 ft on all lines out of a station. It is necessary that this 2,000-ft section be free from direct strokes so that the terminal condenser will be charged through the surge impedance represented in this 2,000-ft section.

It has been suggested[6] that this surge impedance could be replaced by a series inductance at the terminals of the machine. This inductance with the capacity at the machine terminals results in an oscillating circuit and to limit the crest of the voltage wave entering the machine to a safe value it would be necessary to install a lightning arrester on each end of the series inductance.

No mention has been made of the size of the inductance required for this purpose. With the authors protective scheme, a 0.5-μf condenser is sufficient to prevent the reflected voltages at the machine neutral from rising to dangerous values. A series inductance together with the terminal condenser should have approximately 5 times the inductance inherent in a 5 per cent load limiting reactor to provide the same protection. An inductance of this size is impractical. Of course, increased capacity at the machine terminals decreases the size of the inductance required.

For protecting the turn insulation in a machine, the inherent inductance in load limiting reactors together with a small capacitance to ground (approximately 0.1 μf) at the machine terminals usually will be suitable provided that lightning arresters are located at each end of the load limiting reactor. This arrangement should prove desirable for protecting grounded neutral machines.

However, in general, the arrangement using series inductance requires much larger capacitors than the schemes proposed in the paper if the series inductance is to be limited to a reasonable value and hence, the authors schemes should prove to be the most desirable for most installations.

**K. K. Palueff:** By taking the transient voltage characteristics of generators given in the paper by Messrs. Wieseman, Rudge and Lewis and the formula presented by Mr. Hagenguth and the writer a year ago[7] for calculation of transmission of lightning through transformers to rotating machines we were able to get quite a definite idea of the magnitude and shape of lightning voltages that can reach generators connected to transmission systems through transformers.

As shown in the paper referred to, lightning voltages reach generators through transformers by means of electrostatic and electromagnetic induction. The energy associated with electrostatic transmission is so small that the capacitance of the low voltage busses, cables, and other parts of low voltage circuit may reduce the amplitude of voltage very appreciably.

---

[5] Bibliography 2 of paper.

[6] Bibliography 1 of paper.

[7] *Effect of Transient Voltages on Power Transformer Design—IV*, A.I.E.E. TRANS., Sept. 1932, p. 601.

The bulk of the lightning energy is transmitted by electromagnetic induction, and while its amplitude and shape are affected by the constants of the low voltage circuits, it still is able to produce very high voltages of steep fronts.

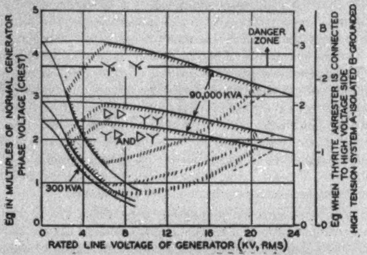

Fig. 6—Lightning Voltage from Generator Terminal to Ground (*Eg*) (Transmitted Through Transformer)

Transformer turn ratio 1:1. Generator surge impedance 600 ohms

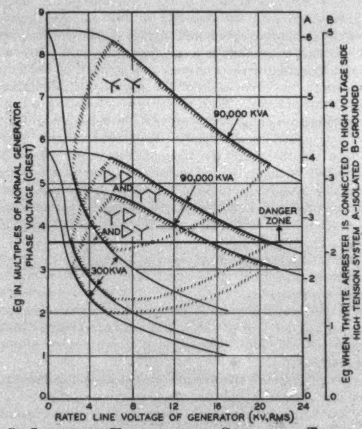

Fig. 7—Lightning Voltage from Generator Terminal to Ground (*Eg*) (Transmitted Through Transformer)

Transformer ratio 4:1 or higher. Generator surge impedance 600 ohms

Voltage transmitted electrostatically may radically be modified by mere change of distribution of the transformer windings on a core. Therefore, no definite idea can be given of the magnitudes of these voltages without referring definitely to a specific type and size of transformer. The electromagnetic induction, however, depends only on turn ratio and the short-circuit reactance of transformers and is absolutely independent of construction features of the transformer. For this reason it is possible to calculate the voltage for practically the entire range of the transformer ratings using for short-circuit reactances of transformers, values typical to the respective ratings.

*Voltage $E_g$ to Ground* (*Figs. 6 and 7*). If the maximum amplitudes of lightning waves that are likely to strike the high voltage winding of a transformer were independent of the length of the waves, then the longest wave would produce the highest voltage at generator terminals. However, on account of the time lag phenomena, the arcover voltage of line insulation and of coordination gap is considerably lower for long waves than it is for the short ones. Thus, it can not be stated apriori whether short or long waves will produce the highest voltage.

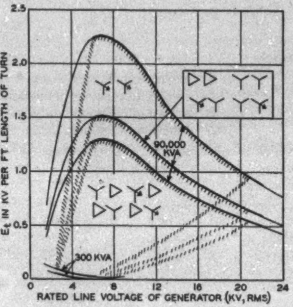
As numerical calculations are quite involved they were confined here to the ½-5 and the 1½-40 waves, and two sets of curves similar to Figs. 6 and 7 were obtained.

It was found that in smaller generators of higher voltage, the 1½-40 wave produces higher voltage to ground that the ½-5, while in larger generators of lower voltages the reverse is true.

Taking in each case the highest of the two voltages, the family of curves of Figs. 6 and 7 were plotted. The amplitudes of waves applied to the high side of transformers were assumed to be limited by a coordination gap and their values therefore were taken to be, for the ½-5 wave 8.55 times the rated phase voltage (crest) of the high voltage winding; and for the 1½-40 wave 5.74 times this value.

Fig. 8—Maximum Rate of Rise *Et* of Lightning Voltage Entering Generator Windings Produced by Impact of ½/5 Wave on High Tension Side of Transformer

Transformer turn ratio 1:1. Generator surge impedance 600 ohms



According to the authors' statement, the allowable impulse voltage from generator terminal to ground is 2.12 times the crest rated line-to-line voltage corresponding to 3.67 times the rated crest line-to-ground voltage. This voltage level is marked in Figs. 6 and 7 with heavy lines as the boundary of the danger zone. The rated line voltage (rms) of the generators is plotted along abscissa while along the ordinate the voltage to ground at a generator terminal is plotted and is expressed in times-normal crest rated line-to-ground voltage of generator. The cross-hatched border encloses the common ratings of generators found in practise. The upper boundary of each area, drawn with a heavy line, corresponds to transformer bank capacity of 90,000 kva. The lower boundary, also drawn with heavy line, corresponds to 300 kva. The left side corner of each area corresponds to 2,300 volts, while the right side corresponds to 22,000 volts. Different cross-hatched areas correspond to different connections of transformer bank. In the transformer connection diagrams indicated on the curves, the high voltage side is on the left. It is assumed that transformation ratio (line-to-line) for Fig. 6 is 1:1, while for Fig. 7 it is equal to or exceeds 4:1. The ratio of high voltage line voltage to low voltage line voltage is the same for all bank connections in the same figure.

The following conclusions can be drawn from these diagrams:

1. 1:1 transformers reduce lightning voltages from generator terminals to ground to safe values in the majority of generators.

The maximum reduction is obtained in Y-delta and delta-Y banks.

2. Lightning voltages on generator terminals increase with increase in ratio of high voltage line voltage to low voltage line voltage until this ratio reaches approximately four. The increase is not proportional to this ratio. The generator voltages are practically independent of it as long as the latter is not materially less than 4.

3. Lightning hazard to ground (major) insulation of generators increases with the kva capacity of transformers connected between high-voltage line and the generator, and with reduction of the rated generator voltage.

4. The surge voltage to ground depends not only on generator characteristics, transformer reactance and turn ratio, but also on the transformer bank connection. The voltage stress in the generator is highest for the Y-Y transformer bank, having both neutrals grounded (or for an auto-transformer) and is lowest for the delta-Y and Y-delta transformers.

5. It appears that without lightning arresters on the high side of transformer, many generators connected to Y-Y, delta-delta, and Y-delta banks having line-to-line ratio approximately 4:1 or greater are in the danger zone.

6. A thyrite lightning arrester on the high voltage side of the transformer eliminates this danger for some of the bank connections, and materially reduces it for others.

*Voltage $E_t$ Across Turn Insulation* (*Figs. 8 and 9*). Voltage between turns depends on the rate of rise of the voltage to ground.

Curves of Figs. 8 and 9 were calculated for the ½-5 μsec wave applied to the high tension side of transformer banks. The 1½-40 wave gives lower voltages.

If mutual inductance between adjacent turns is neglected, then the voltage between turns can be obtained by multiplication of the corresponding value of $E_t$ (of Figs. 8 and 9) by the effective length of the turn (in feet). The effective length of turn is

$$l_{eff} = l_i - \frac{l_a}{18}$$

where $l_i$ is length of turn conductor embedded in slots, $l_a$ is length of conductor outside of slots, 18 is an approximate propagation-constant, which is equal to the ratio of velocity of light to the velocity of propagation of a traveling wave along the conductor embedded into a slot.

If the voltage so obtained is not more than, say 0.66 $E_g$ given in Figs. 6 and 7, then it represents the correct turn voltage. If, on the other hand, this voltage is much in excess of 0.66 $E_g$ it represents voltage in excess of the correct value. In most of the cases it will be found that turn voltage is less than 0.66 $E_g$. The presence of mutual inductance tends to reduce the voltage between turns.

If the value of the kilovolts per foot given in Figs. 8 and 9 is multiplied by 55.4, kilovolts per microsecond are obtained. Different curves correspond to generators of different capacity marked on the curves. It is seen that the turn stress is the highest for the transformer banks of low voltage and high kva ratings and is lowest for banks of high voltage and low kva ratings. Since the strength of turn insulation depends on many factors, it is impossible to draw a danger zone in these diagrams.

It may be added that voltages transmitted through a transformer electrostatically are apt to be much steeper than those transmitted electromagnetically, and therefore are particularly dangerous to turn insulation of generators connected to transformers by means of busses of negligible electrostatic capacitance.

### General Conclusions

With transformer banks guarded only by the coordination gap, the ground insulation of the majority of rotating machines is in danger where they are connected to the transmission systems through transformers with relatively high transformation ratio. A lightning arrester on the high side capable of reducing the incoming lightning voltage to some 70 per cent of the coordination gap level would remove this danger to the generator ground-insulation in most cases, with the exception of the Y-Y grounded neutral transformer (or auto-transformer) banks. In the latter case lightning arresters for the grounded system can be used, and if they are capable of reducing voltages to some 56 per cent of the coordination gap level they will protect the ground insulation of many generators.

However, a lightning arrester on the high voltage side of the transformer capable of protecting the ground insulation of the machine will not, in many cases, protect the turn insulation of the machine as it will not sufficiently modify the shape of the front of the wave. Therefore, to protect the turn insulation a proper condenser should be connected from the generator terminal to ground which would slant the front of the wave transmitted to the generator to a sufficient degree. To eliminate the danger of possible resonance between the protective condenser and the inductance of the circuit, in case of switching, or other oscillatory transients, a thyrite arrester should be placed in shunt with the condenser.

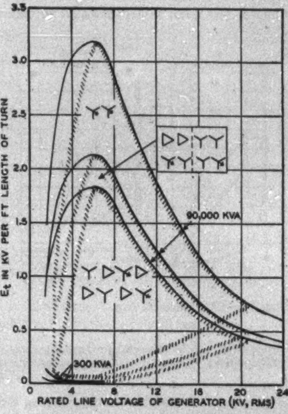


FIG. 9—MAXIMUM RATE OF RISE $E_t$ OF LIGHTNING VOLTAGE ENTERING GENERATOR WINDINGS PRODUCED BY IMPACT OF ½/5 WAVE ON HIGH TENSION SIDE OF TRANSFORMER

Transformer ratio 4:1 or higher. Generator surge impedance 600 ohms

Available formulas permit quite accurate calculation of voltage stresses for any particular installation provided the following data are given:

1. Generator design data. These permit calculation of the surge impedance of the generator and its natural frequency.

2. Arrangement and size of low voltage busses. This permits determination of their effect which is particularly pronounced for voltages electrostatically induced.

3. Transformer kva capacity, turn ratio, bank connection, condition of neutral (grounded or not). This is all that is necessary for the determination of electromagnetically induced voltages. The distribution and dimensions of windings are necessary if electrostatically induced voltages are to be determined.

4. One-line diagram of the substation.

5. The maximum voltage permitted by protective devices (coordination gaps, lightning arresters, etc.) to reach high-voltage terminals of the transformer.

### Impulse Ratio of an Assembled Transformer

The following is a discussion of the paper by Messrs. Montsinger, Lloyd and Clem:

It has been suggested by some that the overall impulse strength of a transformer is proportional to its 60-cycle strength multiplied by the impulse ratio of a barrier of transformer insulation. Such a view is erroneous because it neglects the radical difference in the character and in the distribution of stresses, throughout the complex structure of transformer winding, produced by 60-cycle voltage, from those produced by the impact of an impulse (Fig. 10). This view is no more correct than the claim that the ability of a dirigible to stand a side thrust of a sudden gust of wind can be determined from the uniform steady load test on the dirigible itself and from the ratio of impulse tensile strength to steady load tensile strength of a sample of structural material used for its frame.

If the voltage distribution produced by impulse throughout transformer winding was essentially identical to that produced by 60 cycles, then the impulse strength of a transformer could be judged by its 60-cycle strength. The ratio of the impulse strength to the 60-cycle strength would be the "impulse ratio" of the transformer. This impulse ratio would then be equal to the impulse ratio of the insulating material used and, therefore, could be determined from the impulse ratio test on *samples* of the insulation used. Thus, for example, if impulse ratio of insulation material is assumed to be say 1.85 (this is the ratio of 1½-40 impulse test wave to 3.46 induced voltage test, see Fig. 10A), it could be stated that the transformer as a whole will be able to stand impulse voltage of 1.85 times the maximum 60-cycle voltage that can safely be applied to it. This is so because due to the assumed uniform distribution the impulse voltage between coils, turns, etc., throughout the entire winding would be 1.85 times the safe 60-cycle stress.

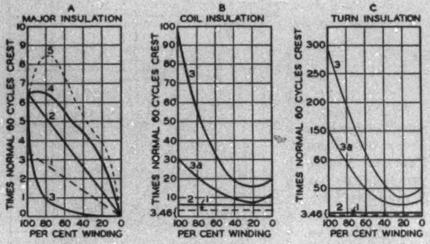

Fig. 10—Comparison of Stresses in a Transformer Produced by Low Frequency and Impulse Tests

Solid lines = impulse test produces non-uniform oscillatory stresses
Dotted lines = 60-cycle test produces uniform steady stresses

Unfortunately, in all transformers with the exception of the non-resonating type, impulse voltage distribution throughout the winding is different essentially from that of 60 cycles. Therefore, when an impulse voltage of 1.85 times 60 cycles is applied to the line terminal, stresses between coils and turns may be 10 or even more times their safe 60-cycle stress (Fig. 10A, B, C). It follows that should their insulation be able to stand only 1.85 times such stress the transformer would fail internally at the application of an impulse wave of 1.85 times 60 cycles. In examining the curves given in Fig. 10 we find that the entire structure except the insulation to ground adjacent to the terminals may be stressed by impulse far in excess of 1.85 times its 60-cycle stress. It is, therefore, impossible to express the impulse strength of a conventional transformer in terms of its 60-cycle strength times the impulse ratio of a sample of insulation. Therefore, two transformers of identical rating and of the same 60-cycle strength, but of a different construction, may have an entirely different impulse strength. For this reason, Fig. 2 of Montsinger, Lloyd and Clem's paper should not be misinterpreted. It illustrates the relation between the impulse strength of a particular insulation barrier and the arcover voltage of a given setting of a rod gap.

The relative values of lightning strengths of the entire insulation structure of a transformer and of a coordination gap, may essentially be different from the one shown in Fig. 3 of the paper, as it depends not only on the strength of the major insulation but also on the strength of coil and turn insulation.

The only conclusions that can be derived from this figure in regard to an assembled transformer is that the margin of safety offered by a coordination rod gap to a transformer is reduced for exceedingly steep waves.

### Detection of Failures Caused by Impulse Test

The transformer subcommittee has made a stride toward the solution of the very difficult problems of commercial impulse testing of transformers. It must be emphasized, however, that the problem is not as yet completely solved. In referring to the detection of dimensionally small damages: extensive damage or a complete failure of major insulation can be detected by methods outlined in the subcommittee's report. However, the puncture of coil or turn insulation, in the majority of cases, cannot be detected by the means recommended by the subcommittee.

It is important to recognize that lightning, both the natural and the artificial, may sometimes produce dimensionally very small damage to apparatus insulation. Such damage in extreme cases may be in the form of pinholes. These punctures often can be detected only with the assistance of a magnifying glass and with a special light, after a transformer is completely disassembled. This may explain why this type of failure is not generally known and even the possibility of its existence sometimes is doubted, although the writer brought this phenomenon to the attention of the Institute as early as 1928 in a discussion[8] which presented arguments in favor of impulse testing of transformers. This type of damage is found in all types of insulation used for transformers and rotating machines.

In this respect, European experience is similar to that of this country. Mr. Norris of Ferranti Ltd., has described[9] the difficulties of detection of local failures in his large 132-kv transformer as follows:

> "After 500 severe surges, there was no external indication that the windings had been damaged by the surge. However, on dismantling the windings and examining them, turn by turn, numerous places of breakdown and partial breakdown were found—all of them between turns and between coils. There was no sign of failure between the high-tension windings and either the low-tension windings or ground."

The writer calls particular attention to the fact that the excitation of a transformer with 60 cycles voltage during the impulse test does not appreciably increase the probability of detection of damages, because the establishment of "follow" power current, under the condition of test outlined in the report is most improbable, particularly in case a failure takes place between turns.

It is possible, therefore, for a transformer unsuitably designed or manufactured to be severely or even mortally wounded during the impulse test in the factory without giving a sufficient indication of the distress to justify its rejection. It may take weeks and even months until one of these local breakdowns will develop into a complete failure under the service stresses.

In view of the above it is hoped that in the near future, a more positive method of determining the condition of transformer insulation after the impulse test will be found. This would place commercial impulse testing on a more firm ground.

### COMPARISON OF 60-CYCLE INDUCED VOLTAGE TESTS WITH IMPULSE

In transformers of ordinary construction, the impulse and 60-cycle tests differ radically in amplitude, duration, and distribution of stresses produced throughout the winding. In transformers of non-resonating construction, they differ essentially only in the amplitude and duration.

Separate comparison is shown in Fig. 10, of stresses produced, in major insulation (insulation to ground), coil insulation, and turn insulation, by these two tests. It is assumed that the applied wave is 1½-40 with amplitude just below that necessary to arc over a standard test gap. The amplitude of the induced voltage test is assumed to be 3.46 times normal phase voltage (rms). All voltages are expressed in multiples of normal voltage (crest).

*Voltage to Ground—Fig. 10*A.

*60-Cycle Test.* Line 1*A* gives voltage for transformers of all types.

*Impulse Test.* Curve 2 gives voltage distribution in an ideal non-resonating transformer.

Curves 3, 4, and 5 give voltages in ordinary transformers. Curve 3 indicates the initial distribution, 4 and 4 the maximum produced by oscillation subsequent to the impact of the wave. Curve 5 corresponds to ultimate voltage that can be obtained in a transformer with a relatively short natural period, while 4 corresponds to a transformer with longer period.

It is interesting that an appreciable lengthening of the applied wave beyond 40 μsec does not lower its amplitude very much as the impulse ratio or arcover voltage of a rod gap for 1½-40 is only some 10 per cent higher than that of a 1½-100 wave.

However, the lengthening of the applied wave from 40 μsec to 100 μsec increases very appreciably the internal voltages to ground in ordinary transformers (curve 4).

*Voltage Across Coils and Turn Insulation—Fig. 10*B, C.

*60-Cycle Test.* These tests produce voltage stress of 3.46 times normal.

*Impulse Test.* Curve 2 shows voltage stresses in an ideal non-resonating transformer. Curve 3 shows the approximate range of stresses in ordinary transformers of different construction and proportions. Location of a given coil or turn in a winding is indicated by the abscissa.

Duration of stresses produced by 60-cycle test is the same for all elements of insulation structure in all transformers. Duration of stress produced by an impulse wave in an ordinary transformer is very different for different elements and for the same elements in different parts of the structure.

One of the conclusions that can be drawn from the above is that no matter what the ratio of impulse of the two tests, they can not be made equivalent in any transformer with the sole exception of a non-resonating type. In case of a non-resonating transformer, the duration of stress is the same for all elements.

### RELATION BETWEEN LENGTH OF APPLIED WAVE AND VOLTAGE TO GROUND

It has been shown before that the internal voltages, from winding to ground, when expressed in per cent of the amplitude of the applied wave, increase with increasing length of the applied wave, until each point of the winding reaches its possible maximum. This possible maximum is indicated by curve 5, of Fig. 10A.

In case the applied wave has a flat top and a sufficiently steep front (say 2 μsec or less) the maximum is reached when the length of the wave is ½ of the duration of the natural period *T* of the transformer. When the applied wave has an exponential tail the maximum, theoretically speaking, is never reached but some 90 per cent of the maximum is produced by a wave which decreases to half of its crest value in about *T* in 2*T* microseconds.

The above relations between the length of the applied wave and internal voltage to ground hold for the middle third of a transformer winding.

It should be appreciated, of course, that different points along the winding require a different minimum length of the applied wave to cause these points to reach 90 per cent of their possible maximum. It can generally be stated that the shortest wave is required for the third of the winding next to the grounded neutral and the longest for the third next to the line terminal.

From this it would follow that to subject the major insulation of an ordinary transformer to the maximum stress, it is necessary to apply as long a wave as possible. In any event, at least as long as *T*.

This would be true provided the applied waves were all of the same amplitudes. However, this is not the case as the amplitude of test waves is assumed to be fixed by the arcover strength of a rod gap of a given setting. On account of the time lag of such a gap, the amplitudes of very long waves are appreciably smaller than those of very short waves.

Thus an increase in length of the wave on one hand increases the values of internal voltages relative (in per cent) to the amplitude of the applied wave, but on the other hand, reduces the amplitude of the latter, and therefore reduces the absolute values (in volts) of the internal voltages.

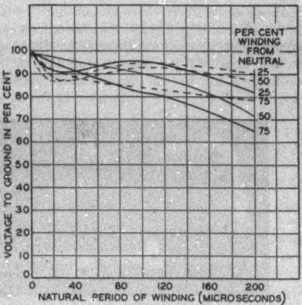

FIG. 11—EFFECT OF THE LENGTH OF THE APPLIED WAVES ON THE VOLTAGES TO GROUND IN WINDINGS OF DIFFERENT NATURAL PERIODS, WHEN THE AMPLITUDES OF THE WAVES ARE CONTROLLED BY A ROD GAP OF THE SAME SETTING

Voltages are given in per cent of the maximum voltages produced by the respective critical waves for 3 points of the winding

Solid lines = 1½ – 40 wave
Dotted lines = 1½ – 100 wave

Numbers on curves indicate the distance of the points from neutral in per cent of total length of winding

The conflict of these two phenomena results in the existence for each transformer of a wave of critical length which produces the maximum absolute stresses within parts of the windings. Waves shorter or longer than the critical produce lower stresses. However, there is quite a wide range of waves on both sides of the critical length that produce voltages within a few per cent of the maximum.

These considerations permit the calculation of the curves shown in Fig. 11. Three curves correspond to 75, 50 and 25 per cent point (measuring from grounded neutral) of a winding, they show the voltages produced in transformers of various natural periods, by a 1½-40 μsec wave (recommended by the subcommittee as standard for impulse test) and by a 1½-100 μsec wave.

The voltages are expressed in per cent of maximum voltage produced at the same points of the winding (of a given natural period indicated by the abscissa) by waves of the respective critical lengths.

The curves indicate that the recommended waves subject the internal major insulation practically to its maximum possible service stress in transformers of natural periods not much longer than say 100 μsec (corresponding to a natural frequency of 10,000 cycles and higher).

In transformers with materially longer natural periods the applied wave must considerably be longer to duplicate the possible internal service stress. It appears therefrom that the 1½-100 wave in contrast with the 1½-40 wave would subject practically all transformers to stresses of essentially the same relative severity, since the natural period of the majority of transformers is less than 200 μsec.

The above analyses were made for transformers with grounded neutral. Essentially the same relation holds for transformers with isolated neutral or connected in delta. The difference in details for the two phenomena is believed to be sufficiently obvious to make further discussion of it here unnecessary.

**F. J. Vogel:**[*] In the formulation of standards or rules for testing, it is necessary that they be sufficiently severe to give reasonable assurance that the apparatus will withstand service conditions, and that the fact that the apparatus has or has not fulfilled the requirements can reasonably be certain of determination. The question of severity in the case of surge testing hinges upon the test gap length, the magnitude of the surge impressed, the polarity of the surge and the shape of the wave. These factors should be chosen with the idea that they would result in transformers of adequate strength for service conditions.

However, some of these factors have been questioned. The proposed test gap insures that there is a margin between the coordinating gap and the apparatus. The magnitude of the test, as determined by the present proposals, in the writer's opinion probably is low for the higher voltage classes, because the proposed rule of 10 per cent above the full wave value of the test gap does not provide a test up to the strength of the major insulation. The polarity of the wave has been questioned. This, however, involves more than just the polarity but also the preceding recommendations, provided obtaining proper insulation of the transformer is the sole thing in mind. It is not believed that this is an essential point in the obtaining of good transformers. The choice of the wave shape is dependent upon two factors. One is the possibility of producing the wave and the other is the question of what represents the worst conditions in service. The steepness of the wave front which may be obtained is limited by the transformer and the surge generator, as has been shown by Mr. Bellaschi (TRANSACTIONS A.I.E.E., December 1932, page 936). Nevertheless, the gap flashover close to the transformer leads to the highest coil stresses and so similar effects to those of the steepest wave fronts can actually be obtained. The length of the wave is dependent upon the inductance of the transformer and the capacity of the surge generator. A long wave can be obtained therefore provided the surge generator capacity is sufficiently great. The criterion for this is the length of the longest surge expected in service. From field data which have so far been collected, there are no indications that lightning surges longer than 40 microseconds to half value will be found in service.

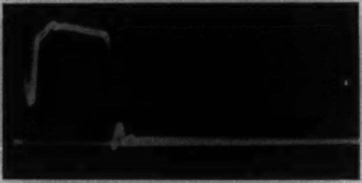

FIG. 12—CATHODE RAY OSCILLOGRAM SHOWING OSCILLOGRAM WITHOUT INDICATION OF INTERNAL TRANSFORMER FAILURE

It is of interest that in the discussion the question of the length of wave is raised. Considerable pains are taken to show that a transformer with a long period does not develop oscillations to the fullest extent with surges of relatively short lengths. This theory was advanced by Mr. J. K. Hodnette in 1929 (TRANSACTIONS A.I.E.E., January 1930, page 68). In the discussion of Mr. Hodnette's paper, some engineers claimed that the maximum full wave lightning voltages were high enough and the period of all transformers short enough so that the grading of insulation was hazardous. Since then, the maximum lightning voltages seem generally to have decreased more nearly to Mr. Hodnette's values. It has also been discovered and agreed to by all engineers that some transformers do have relatively long periods, as Mr. Hodnette claimed. It is apparent therefore that grading of transformer insulation may not be hazardous provided the wave is of the order of 40 to 50 microseconds to half value. No records of natural lightning have been produced so far as the writer knows where the wave is more than 40 to 50 microseconds long to half value. No reason for increasing this value in the Test Code can be seen unless it be to impose an artificial difficulty in the way of certain meritorious designs.

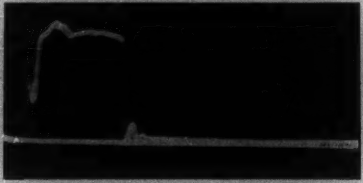

FIG. 13—CATHODE RAY OSCILLOGRAM, INDICATING FAILURE BY THE SLIGHT DEPRESSION IMMEDIATELY AFTER THE CREST OF THE WAVE

Compare this with Fig. 12. This indication is very sensitive of any coil-to-coil damage near the line end of the transformer

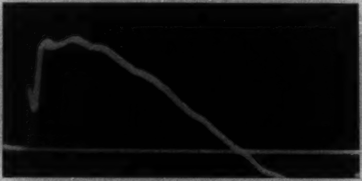

FIG. 14—CATHODE RAY OSCILLOGRAM, SHOWING COMPLETE FAILURE OF THE TRANSFORMER

In this test, a wave as high as that in Fig. 13 was impressed, but the gap did not flash over. Two indications of failure were obtained simultaneously

The question of certainty of detection has been raised by several engineers. It appears that extensive damage or complete failure of major insulation can be detected by the methods outlined in the subcommittee's report. Another believes that puncture of coil-to-coil and turn-to-turn insulation, in the majority of cases, cannot be detected by the means recommended. This does not agree with the writer's experience, and the cause must be that it is not based on the same equipment and methods. If it is caused by difference in design practise, it certainly is a serious matter. It is no less serious if due to lack of experience or technique in testing and observation. It is to be hoped that these difficulties will be removed by further testing experience.

---

[*] Discussion on *Progress Report on Impulse Testing of Commercial Transformers.*

The company with which the writer is associated has tested many transformers up to or higher than the surge voltages which are recommended by the Transformer Subcommittee. These have been distribution transformers, core type transformers with small round wire coils, core type transformers with ribbon wound coils, and shell type transformers. Some of these have been given a great number of tests, a thousand or over in the case of some distribution transformers, and when disassembled with the greatest care, no visible signs of deterioration were found. However, a number of transformers have failed, as indicated by the means available. It may be possible to design a transformer between these limits, which requires some responsibility to be assumed by both the manufacturer and the purchaser.

The experience of an English engineer, Mr. Norris, has been cited. It is my opinion that if the transformer described by Mr. Norris had been tested with excitation, or if cathode ray oscillograms and oscillograms of the excitation voltage and current were obtained and other means used as described in the subcommittee's report, indications of the extensive failures described would have been obtained. It is clear on the one hand that such tests were not possible in 1930 and on the other that transformers built in 1930 and possibly incapable of withstanding surges can be replaced in 1933 with transformers capable of withstanding repeated surges.

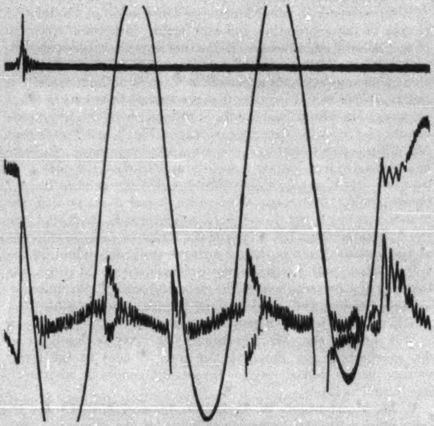

Fig. 15—Oscillogram of Excitation Voltage and Current During a Transformer Failure

The top line is an indicator only to show the instant that the surge occurred. The middle wave shows the current flow, which flowed for 2½ cycles after the surge occurred. The lower-line shows the disturbance to the voltage wave. Power follow is rarely continuous, but does do further damage, even when it occurs locally, and for a part of a cycle only

The writer cannot agree that excitation does not increase the probability of detection of failure. In the case of a single failure between turns, with no further testing, it could not be said to be a definite indicator. But in actual practise, such a failure soon involves other turns and enhances the probability of power flow, even for a fraction of a cycle. In a station, lightning struck a tower close by, and one of the transformers failed. The failure involved one coil only. No damage was found elsewhere. If power had not been available, it is felt that nothing would have happened. The bank was delta-connected and only one transformer showed evidence of failure, although two were subjected to the same surge voltages. In the other one, due to the phase position, power did not follow. This clearly shows the value of power-follow testing. We have found that in failures of some transformers some indicators are more sensitive than others, and that power-follow is a very essential indicator. We have taken oscillograms of the low voltage current in most transformer tests, to show the time of the surge, and to show any power flow taking place. Examples of oscillograms taken during transformer tests are shown in Figs. 12 to 15.

The statement has been made that surge tests are more sensitive, if anything, than the present 60-cycle or induced tests. This is believed to be true.

Another engineer has cited the case of three transformers, *A*, *B* and *C*, where *A* fails through the major insulation but where *B* and *C* apparently pass the test. *B* further is assumed to be damaged but *C* to be good. If this can be the case, it is stated that the test without a detector is worse than useless. This statement would not universally be agreed to even without as sensitive a detector as we now have. A potentially dangerous piece of equipment was detected (transformer *A*). Transformer *B* would be in no worse shape then after the first line surge had struck it, and at worst but a small proportion of its possible life has been taken away. Actually, however, there will be few transformer *B*'s. Nevertheless, there is a suggestion here. Possibly the correct surge test would consist of repeated tests, which would increase the incipient damage done until actual failure by power follow or other indication, to make it more comparable in length to the 60-cycle tests.

**F. J. Vogel and V. M. Montsinger:** The subcommittee was very glad to get so many discussions of the report. As may be inferred from the title, the report merely marks progress. We realize that it will, no doubt, be necessary as time goes on to make changes and modify it as we gain further experience.

Most of the points mentioned by the discussors have been considered by the subcommittee. However, this does not mean that these suggestions will not be given further consideration. One or two points in particular may be mentioned. Mr. Sporn suggests that negative waves instead of positive waves be used since in practise the highest lightning voltages are of negative polarity. The best argument for using negative waves is not the one mentioned but that the negative wave flashovers of most insulators and coordination gaps are higher than positive wave flashovers. However, unless the stresses imposed in windings by a negative wave are more severe than those imposed by a positive wave (of the same voltage amplitude) the question of polarity of waves merely is one of severity of test or of what level of impulse voltage should be used in making the impulse tests. So far as we know there is no difference in the stresses imposed by either wave of the same amplitude. Therefore, what Mr. Sporn really suggests is that the impulse level for testing be raised.

When establishing the level of the test gaps the committee felt that these gaps imposed as severe a test as was justified at the present time. We have no assurance, it is true, that the tests proposed are of adequate severity. If further experience indicates that it is desirable and necessary to raise the impulse level, manufacturers will be very glad to do so.

As to the suggestion that volts instead of gap spacings be used, the subcommittee as stated heretofore has given this very careful consideration. The committee recommended the method which it was felt would come nearest giving the same results when used by the various laboratories.

When the different laboratories can check each other in kilovolt values the subcommittee again will consider changing over to volts. Actually, we do not see why the use of the gap as a measure of impulse tests should be objected to as it fulfills its intended purpose very well indeed.

The other points raised, including the question of detection of damage, etc., will be referred back to the subcommittee for further consideration.

In conclusion, the subcommittee appreciates very much the suggestions offered. It is felt that it is progressing along the right lines, and that the present proposals should be given one or two years trial before attempting to make any material changes.

**F. J. Vogel:*** Mr. Brand has brought up the point that due to the relations of transformer insulation and the coordinating gaps at the very short time lags, the impression may be obtained that the whole scheme of insulation coordination using gaps is of little value. Mr. Brand has given important reasons why this impression is not justified. The original intent of the coordination work was to provide coordination for traveling waves, and not direct strokes, as may be recalled from the original recommendation of reduced line insulation for one-half mile from the transformer. As Mr. Brand has stated, extremely steep fronted surges are not to be anticipated, because of distortion from corona loss, and also because of the lumped capacitance of the station and transformer. These views are confirmed by the remarks of Messrs. Fortescue, Peek, Putman and others. It is essential therefore to protect stations from direct strokes by ground wires, in which case the present coordinating gaps will serve as real protection to the transformers and equipment if properly installed.

Mr. Sporn has raised three points, which are discussed as follows:

*1. Strength Against Negative Waves.* To the best of the writer's knowledge, no data for the strength of transformer insulation against negative waves are or have been published. There are no data in the paper by Messrs. Montsinger, Lloyd and Clem for the strength of transformer insulation against negative waves. The statement is made in their paper that "polarity also affects the flashover, the negative wave *usually* requiring the higher voltage." No question of this statement is raised, as it is true usually, but exceptions do arise. Mr. Sporn does not feel that it is shown conclusively that the strength of transformer insulation is approximately the same for positive and negative waves. It always is a question as to the amount of data required to be conclusive. For the purpose of the paper, I believed the data provided to be sufficient, but it is proved further by tests I have made on transformers and other data not easily presented.

However, reference to Fig. 9 of the paper will show that the negative points preponderate above the line and the positive below, and there is reason to believe that there is a slight difference, possibly as much as 5 per cent in favor of the negative wave. Considering the variations in individual readings, it was not felt desirable to claim such a difference, and it was necessary to state that the results for negative and positive waves were only approximately the same.

*2. Present 60-Cycle Tests.* The surge strength of transformer major insulation and of the coordinating gaps has been determined in the laboratory, both by tests on insulation samples and in specific instances by tests on transformers. Mr. Sporn's unsatisfactory experience can be explained in several ways. The paper specifically limits itself to *major* insulation, and it is possible that the windings of his transformers were relatively weak. Lightning arresters of various manufacture and age are not uniform in performance, and in all cases must be installed properly to be effective. Coordinating gaps must also be installed with due regard to location and grounding. Further than this, it has been shown possible with extremely short waves to cause simultaneous gap and bushing flashovers, and it requires no stretch of the imagination to explain a failure of the coordination system by a direct stroke of lightning.

*3. Lightning Arrester Recommendations.* In former years laboratory data to show that lightning arresters were effective were not available. It is now a simple laboratory experiment to surge test a transformer and an arrester in parallel with the coordinating gap, and show the relationships which are claimed. Whether an arrester is justified economically may be questioned in some instances, but that it will perform the function of preventing flashover of the coordinating gap in a transformer installation can readily be demonstrated.

Several have brought out the point that windings may not be insulated up to the level of the major insulation as determined by the 60-cycle standard disruptive tests. I had believed that I had placed special emphasis on this point. Nevertheless, the reemphasis placed upon this point by Mr. Montsinger and Mr. Palueff cannot help but be beneficial. However, I would like to bring out the fact that the impulse ratios of all insulations, even under oil, are not the same, and that under no circumstances can the fact that a transformer has withstood the standard overpotential and induced tests be used as evidence of its surge strength. It is not always economical or desirable to design transformers with even approximately uniform surge voltage distributions, and this constitutes another reason for making surge tests on transformers.

With reference to Mr. Montsinger's discussion of the relative shapes of the coordiating gap and major insulation time lag curves below 2 microseconds, it does not appear that his generalization is safe. I have tested transformers and models at very short time lags against the coordinating gaps without insulation failure, which would indicate that the shape of the curves is not always as Mr. Montsinger shows. I believe, therefore, from these results and from the data on my curves, Fig. 3 and Fig. 5, that Mr. Montsinger's tests and my own were not made on comparable structures. Also, it is to be noted that the time of 2 microseconds is not definitely stated, but it is stated as *about* 2 microseconds. Reference to my Figs. 3 and 5 shows that the curves are flat down to about 2 microseconds, and that the closest relationships (allowing for the factor of safety) will exist at times somewhat less than 2 microseconds, depending on the voltage class, and also upon the construction used. Care was taken in the presentation of the data and analysis to make allowance for some variations, and not to make an exact statement which could not be shown generally to be true.

It is pleasing that Mr. Montsinger has come as closely as he did in checking my proposals for test voltages in the lower voltage classes, considering the present differences in laboratory results and methods.

**V. M. Montsinger, W. L. Lloyd, Jr. and J. E. Clem:** In connection with Mr. Putman's criticism of the statement that the gap is considered as a device for setting a maximum to the voltage which may be applied to the station apparatus, we can not see why this statement is criticised because even though the gap does chop the wave it certainly limits the incoming voltage to a lower level than if it were not present. The word "limit" does not necessarily mean that it maintains the voltage at a constant kilovolt value regardless of wave shape.

In his remarks about the coordination gap not being a protective device, Mr. Putman indicates that he has missed the point entirely, while Messrs. Sels and Beck agree with the authors. The requirements of ideal protective equipment needed can be formulated without reference to transformers. They are: (1) goes into operation at a voltage in excess of the operating voltage; (2) maintains a liberal margin below the strength of the apparatus; (3) does not cause any additional voltage strains, either of magnitude or gradient; (4) does not cause a system outage; and (5) is not damaged itself. The plain gap has been tried and found wanting in some of these respects. The coordination gap serves as a basis of design and test at the factory and in the field as a measure of the minimum protection required. The choice of the protective equipment must rest with the purchaser who is responsible for the safe and successful operation of the apparatus.

Mr. Putman criticises our wording on protection offered by sphere gaps. What the paper really says is that by using the

---

*Closing discussion on *Factors Influencing the Insulation Coordination of Transformers.*

sphere gap a more nearly constant factor of safety is maintained throughout the range of waves than if only a rod gap is used. We do not believe that Mr. Putman can question this statement.

In connection with the suggestion that it would be better to locate the coordination gap some distance away from the transformer we believe that two gaps are preferable, the one further away being set slightly higher than the one near the transformers. Taking everything into consideration it is quite desirable to have at least one gap as near the transformer as possible.

Mr. Sels suggests the use of sphere gaps for impulse testing of transformers on the basis that the time lag curve of the sphere gap is more nearly the same as that of the transformer interior than is the time lag curve of the coordination rod gap. This is a good argument and one which cannot lightly be cast aside. However, since the time lag curve of line and bus insulators is more nearly the same as that of the rod gap, it seems better to use a rod gap for the measurement of the test voltage. However, should a design of coordination gap be worked out using a sphere gap in parallel with a rod gap then it would be quite logical to make the impulse test with such a gap.

We agree with Mr. Sels that the coordinating gap has one undesirable feature; namely, it produces tripouts, and to avoid this we recommend the use of lightning arresters which are intended to prevent the gap flashing over.

We feel quite sure that Mr. Sporn's ideas and ours in regard to the establishment of a uniform level of station insulation are identical. The major parts of the station insulation consist of the bus supports, disconnecting switch insulators and apparatus bushings. A bus short-circuit can be just as disastrous when it is initiated by the flashover of an apparatus bushing as it is when caused by flashover of the bus insulator itself. Therefore, nothing is gained by increasing the flashover of the bus insulation if flashover of apparatus bushings can cause a bus short-circuit. However, if the apparatus bushings can flash over without causing a bus short-circuit, it is obvious that short-circuit can be prevented by increasing the bus insulation. No doubt this is the situation which Mr. Sporn has in mind.

In answer to Mr. Sporn's question (3): briefly, a cable will be a protective device when its capacitance is such that it can reduce the crest of the surge and its front to values that are harmless to the connected apparatus. This question has been fully discussed in a paper entitled *Traveling Wave Voltages and Cables* by Brinton, Buller and Rudge and the discussion by Clem published in the TRANSACTIONS, March 1933 on pages 121 and 129.

Mr. Sporn again raises the question as to why coordination is not as yet made exclusively on the basis of volts. Of course, this is the logical course and is the goal toward which we are all working. At present, however, it is quite clear that the rod gap is the best means of getting along. The reasons for this have been given in the paper.

Mr. Vogel cites the case where the impulse ratio of varnished cambric is somewhat lower than that of pressboard and oil in series, which was used in his replica of major insulation and in the insulation barrier cited in our paper. While it is true that the impulse ratio is not always the same for various materials the insulations used in our transformers for major insulation are generally herkolite cylinders and herkolite flanged collars or pressboard employed on the outside of the windings for shields, etc. These materials have approximately the same impulse ratio. We do not depend on varnish cambric for major insulation.

In connection with determining the time lag of the sphere gap shown in Fig. 2 the voltage values shown obviously were not taken by a sphere gap but were determined by the divider deflection. The divider resistance ratio was not used but the ratio was determined by independent sphere gap calibration, It is true that in making these measurements a great deal of care was necessary to overcome errors due to corona so that the special divider had a very high degree of fidelity.

As stated in the discussion of Mr. Vogel's paper the impulse value of 2.35 was obtained on other insulation and winding set-ups long before the tests were made on the particular barrier as cited in the paper.

It does not seem that Mr. Vogel is very consistent in advocating that the lowest values should be given the most weight when he found an impulse ratio of 1.63 for the varnished cambric, and at the same time gives an impulse ratio of 2.2. Mr. Vogel does not make himself very clear where he states that "for shorter and shorter time lags the impulse ratios of all elements approach infinity, and infinity over infinity is rather an indefinite indeterminate ratio to use to determine the factor of safety." The impulse ratio as generally understood for solid insulation is the ratio of the impulse breakdown divided by the 60-cycle one-minute breakdown kilovolt. We agree with Mr. Vogel's suggestion and our paper states that the ground wire protection should be provided over stations as a protection from direct strokes. However, there are some fairly high voltage outlying stations where the expense required to provide either lightning arresters or overhead ground wire protection cannot be justified. Our suggestion is that for these cases the next best thing is to provide a combination coordination gap which has volt-time characteristics similar to transformer insulation, thereby maintaining a more constant factor of safety regardless of the lightning wave shape.

We also agree with Mr. Vogel's suggestion that the combination protective device gap should be protected by a lightning arrester. This device then not only protects the transformer but protects service from outages. He points out, that in Table IV the ordinary sphere gap is impractical due to its size. For 220-kv circuits it may be impractical to use one meter spheres but for circuits of 138.5 kv and below the sizes of spheres required do not appear to be impractical at all. However, it is practicable to get sphere gap protection for any voltage by using several small spheres in series as mentioned in the paper and as outlined in Mr. Palueff's discussion.

In connection with Mr. Vogel's criticism of Table V we would again like to emphasize the point that we can make no definite claims for any protective device under the most severe direct stroke but that the use of the sphere in combination with a rod gap certainly will tend to maintain a more constant factor of safety and it is this feature which makes the sphere gap look promising.

The terms "outdoor" and "indoor" *versus* "exposed" and "unexposed" have their advantages and disadvantages. We considered that the terms outdoor and indoor were preferable, but we are open to suggestions for better terminology.

The value of 4 in. given in Table I for 13,200 volts is incorrect. It should be 4¼ in. on the basis that 13,200-volt equipment is in the 15,000-volt class.

With reference to Fig. 4, curve *D* represents the equivalent rod gap of our present power transformer bushings. Curve *C* is proposed as a standard level. If power transformer bushings can be brought down to level *C* without considerably decreasing the 60-cycle wet flashover values by means of a gap, it may be found possible in the future to line up all transformers with curve *C*. Mr. Vogel apparently objects to gaps on bushings for two or three reasons, none of which we believe are really good reasons. We would call Mr. Vogel's attention to the fact that it is now and has been standard practise for several years for some of the European manufacturers to gap all of their bushings, these gaps being provided primarily as a protection to the porcelain in case of power arcs. If the impulse flashover of bushings is to be standardized, and there does not seem to be any question but that they should be, the use of gaps will become an absolute necessity to take care of length variations in bushings of different manufacturers. They should be welcomed by both manufacturers and operators.

We agree with Mr. Beck's suggestion that the use of a lightning arrester in combination with a coordination gap is very desirable because it flattens out the wave and acts more nearly like a sphere gap in this respect. This is true particularly of modern thyrite arresters. However, we do not believe that the manufacturer of either autovalves or thyrite arresters will claim that even a modern arrester can always handle the most severe direct strokes. It is for this reason that it is suggested that the sphere gap might be used to advantage where ground wire and direct stroke protection is not practical. While the paper states that the best sphere gap protection can be provided with covered spheres yet it is not absolutely necessary in all cases that the spheres be covered to give considerable added protection. As pointed out in the paper the low frequency flashover can be held under rain conditions to with 3½ to 4 times normal voltage with uncovered spheres. Under dry conditions this corresponds to about 8 times normal voltage. It is shown that even with this setting considerable protection is offered for really steep front waves. Mr. Beck suggests the use of the gaps patented by Allcutt some years ago. Our paper points out the possibilities of using two or more gaps in series shunted by capacitance and resistance. While these special combination gaps may be used, our tests indicate that in view of the very close agreement in the volt-time characteristics of the sphere gap and insulation from the standpoint of maintaining a constant factor of safety there is no gap better than the sphere gap for this purpose.

Mr. Fielder questions the accuracy of the humidity correction curves as determined from the data points given in Figs. 7 and 9. The actual slope of the curves was determined not with the few points listed, but with a very large number of points taken under slightly different conditions. Therefore, the slope of the curves was fairly accurately determined. A large amount of data for negative polarity has been obtained and nothing to date indicates that the humidity correction for negative polarity is different from the corrections for positive polarity. The same corrections have been used for both. Should additional data indicate the desirability for modifying the values proposed we will, of course, make the necessary changes.

We have believed in the past and still have every reason to believe that the sphere gap is sufficiently accurate for impulse voltage measurements when the crest voltage of the test waves that are in use at the present time are being measured. The time-lag of the sphere gap as indicated in Fig. 2 was obtained by applying overvoltage to the spheres: they were arcing on the rising front of the wave which reached a crest value in 1.5 $\mu$sec. The curve was obtained by comparing the oscillogram deflections of the sphere arcing on the front of the wave with deflections obtained with the spheres arcing on the crest of the wave. Voltage as measured by the oscillograph is considered accurate when it is referred to sphere breakdowns on the crest of the waves at approximately the same voltage. It is felt, however, that the ohmic ratio of the oscillograph voltage divider can not be used by itself to obtain kilovolt values since the effective ratio changes throughout the wide range of test voltages; and changes with the wave shape.

Mr. Monteith points out that data obtained from the United States Weather Bureau indicates that humidities as high as 9½ grains per cubic foot have been recorded. This fact is not questioned. We do not feel that it is either necessary or economically advisable to increase the insulation and accordingly the cost of apparatus to take care of these few exceptional cases. If the industry desires this extra insulation the manufacturer certainly will have no objection.

Mr. Monteith's curves showing glaring inconsistencies in equivalent gap spacings, emphasize a point which is somewhat outside the scope of this paper and that is—laboratory practise and technique should be standardized. If the different laboratories can not agree any closer on these equivalent gaps than indicated by Mr. Monteith it is no wonder that they do not agree on kilovolt values. The trouble apparently is not with the gaps but with the methods of making the tests. These large differences emphasize the need of some simple method of defining insulation levels. There is nothing more simple than an air gap.

Mr. Monteith's suggestion of the use of kilovolt values plus a correction factor for humidity is of course contingent on the ability of the laboratories being able to get the same kilovolt for the same test piece.

The authors of this paper are rather surprised to note that the burden of defending the action of the Transformer Sub-Committee recommending the use of the point gap for coordination purposes has fallen on them. In view of the discussions presented, the authors feel it desirable to express their views which are as follows:

1. The logical basis of expressing the impulse strength is in kilovolts.
2. The method standardized by the Institute for measuring voltages is the sphere gap.
3. Since one large manufacturer (see discussion by Fielder) does not use the sphere gap, difference in the value of kilovolt given for the flashover of this same test piece has resulted.
4. In spite of this difficulty it is necessary that the industry carry on.
5. The use of the point gap with the flashover value expressed in inches rather than in kilovolt offered an expedient for establishing the design and test level of transformers to tide us over until such time as kilovolts could be used.
6. The use of the point gap with the flashover value expressed in inches minimizes the effect of slight differences in wave shape, and the effects of atmospheric conditions.
7. It is believed that impulse testing of transformers should be based on the rod gap until the technique of the different laboratories can be standardized to the point where the same kilovolt for the same test piece will be given by all laboratories for the 0.5/5 wave as well as for the 1.5/40 wave.

**C. F. Harding and C. S. Sprague:** Within the last few years much progress has been made in the field of surge protection of the lower voltage distribution transformers, both in the modification of the design, and in the methods of protection employed in service. Except for statistical records kept by a few of the larger operating companies, this phase of lightning protection was more or less neglected until comparatively recently. However, the results of the researches of the last few years, and the cooperation of the transformer manufacturers in modifying the designs for improved surge-resisting characteristics, indicate that a practically surge-proof distribution transformer is now an accomplished fact.

It is gratifying to note, in the discussion by Mr. D. W. Roper, that the interconnection of the secondary neutral and lightning arrester ground, which was strongly recommended in several papers, including those of the authors of this paper, at the winter convention of January 1932, has been showing up so well in the cases where this "interconnection" was made.

Referring to Mr. Hodnette's limitations of the favorable use of the interconnection of the secondary neutral to the primary lightning arrester ground, it should be noted that the necessity of multiple low resistance secondary grounds was emphasized in our paper. His general limitation of such an interconnection in cases making use of delta-connected power secondaries may be unnecessarily rigorous, however, since such secondaries with the mid-point of one phase grounded, in accordance with Chicago practise, represented one of the most favorable protective applications of the interconnections tested. The use of secondary arresters is recommended to avoid excessively unbalanced potentials in this case. Considerable protection is provided by the interconnection, however, without these arresters.

The discussion by Mr. Opsahl would represent a correct interpretation of the two oscillograms presented in the paper if a failure of insulation to ground were under consideration but the type of failure of insulation reported in our paper, *i.e.*, "primary winding . . . broken down between turns or layers" was not only apparent from the comparison of Figs. 5 and 9 of our paper but more forcefully evidenced in the many other oscillograms of these same tests not available for the paper, several of which are reproduced in *Bulletin No. 42* upon this subject recently published by the Engineering Experiment Station of Purdue University.

Table I of the paper indicated the protective features of normally-operating arresters with several makes of transformers. It should be noted that the arrester connection used was equivalent to the use of the interconnection in service, and that under this condition, a good protective factor of safety was obtained even with some of the older-style dirt-covered transformers.

Data were presented in the paper on the wet and dry, surge and 60-cycle flashover values of the bushings of various makes of transformers. It is believed that data of this type, although known to manufacturers, are helpful to and desired by the various operating companies, which are not usually in a position to be well informed on the comparative merits of various transformers. Such, therefore, was the principal purpose of this paper.

**R. W. Weiseman:** The limitations of protecting a machine with a series inductance at the machine terminals as outlined by Mr. E. M. Hunter are in agreement with our paper.

Messrs. Palueff and Treat emphasized the need of machine protection even though the machine is insulated from the line by a transformer. In fact as we look back over the past performance of machines that we thought were protected by transformers, it was perhaps more good luck than good management that more failures on these machines were not encountered.

With reference to Mr. J. F. Calvert's questions in regard to the impulse test data, tests were made on machines with the rotor in the stator and with the rotor out of the stator. All tests were made on machines with multiturn coils. The voltage of the machines tested included the complete range of machine voltages and the slots of the machines did not have similar proportions. We are not in agreement with Mr. Calvert's statement that the transmission line theory will give moderately accurate voltage data at the ends of the winding, but no accuracy at all for other points in the winding. The voltage to ground taken at regular intervals along the winding by a cathode ray oscillograph proved conclusively that the errors involved in this method of calculating the voltage to ground are very small.

In conclusion we emphasize the fact that the benefits of rotating machine protection will be realized only when the protective equipment is installed with the machine. In other words, we can't expect protective apparatus to rejuvenate an armature winding after it has been subjected to and perhaps weakened by surge voltages for a number of years.

# Recommendations for Impulse Voltage Testing*

***Synopsis.**—Much of the data on impulse voltage testing of insulators and insulation which has been given out in the past has been obtained on a basis that renders it of little value for purposes of comparison and coordination. To clarify this situation the lightning and insulator subcommittee of the A.I.E.E. power transmission and distribution committee has conducted a study, the results of which are reported in this article. In this report the committee: outlines the present status of impulse voltage characteristic data for insulation; recommends a set of preferred test waves for laboratory use, discussing the use of these waves and test procedure with a view to obtaining comparable and coordinated characteristics of insulation; points out some of the limitations in securing impulse voltage characteristic data, and in the effective use of this data; and indicates the necessity for obtaining impulse data on a logical, accurate, and common basis, pointing out the benefits to be derived therefrom.*

* * * * *

IMPULSE flashover data on insulators, which some 10 years or so ago could be secured in only 1 or 2 laboratories, today are obtainable in some 6 or 8 laboratories in this country. In addition at least 2 electric utilities now own and operate their own lightning generators. With this increase in the number of lightning laboratories, it was found that the data obtained and given out were not comparable, apparently because of the different types of lightning generators and circuits employed and the varying test conditions and setups, and particularly because of the different shapes of the impulse waves employed. These varying data were interesting so far as they showed that the impulse voltage characteristics of insulators were different from the 60-cycle voltage characteristics; however, the major possible benefit that might have been obtained from such data was vitiated because the data could not be applied directly in any design or application work, since no means of checking or determining their accuracy and reliability were available. Practically no 2 sets of data from 2 different laboratories were obtained on a common and comparable basis.

Intensive field research on natural lightning and the invention of the cathode ray oscillograph made possible 2 things:

1. Approximate determinations of the voltage wave shapes produced on transmission lines by natural lightning.
2. A determination in the laboratory of both the actual shape of the applied voltage wave and the point on the voltage wave where insulation breakdown occurs.

Both of these factors, wave shape and point of breakdown, or time, must be considered to obtain a complete and effective application of impulse test data.

It is now known that the polarity of the impulse wave, barometric pressure, and also the humidity of the air, affect the insulator impulse sparkover; it is known further that these factors affect different types of insulators to a different degree. While in some cases these factors have small influence on sparkover values, the effect may be great enough to prevent successful coordination or grading of insulation within practical and economical limitations, if the variations are not considered and properly allowed for.

## PREFERRED TEST WAVES

It must be evident from the foregoing, that present data on impulse characteristics of insulators, protective gaps, etc., are available in such an incomplete form that they cannot readily be applied and used by those responsible for the design and successful operation of transmission and distribution systems and associated apparatus. It is the hope of the committee that the test waves and test procedure recommended here will be adopted generally, and will result in more rapid progress being made in the future in the accumulation of impulse data on a common, accurate, and comparable basis. It is hoped that this in turn will make possible the intelligent utilization of these impulse data in the art of generation, transmission, and distribution of electric energy so that both the power industry and the industries associated with it will benefit.

In order that the lightning flashover and puncture strengths of insulating members may be determined properly, the following are required:

1. Impulse test waves of definite and known shape.
2. The use of a sufficient number of wave shapes to allow lightning conditions in the field to be simulated at least approximately.
3. The use of wave shapes reproducible in laboratories within reasonable limits.

This committee recommends, therefore, that as far as possible, the impulse strengths of insulating members be determined from tests made with the following 3 wave shapes:

1x5 μsec        1x10 μsec        1½x40 μsec

The first number in each designation indicates the length of the wave front in microseconds measured from zero voltage to the crest of the wave; the second number is the designated length in microseconds measured from zero voltage to that point on the wave tail at which the voltage is equal to *half* crest voltage. The reasons for designating that both the fronts and lengths be measured from zero voltage are: (1) the usual equations for impulse circuits determine time from the zero point; and (2) so that a common basis of reference may be established. The 1x5-μsec wave is recommended to replace the ½x5-μsec wave recommended in the 1931-32 report of this committee because of difficulties encountered in securing the ½x5-μsec wave in all laboratories.

---

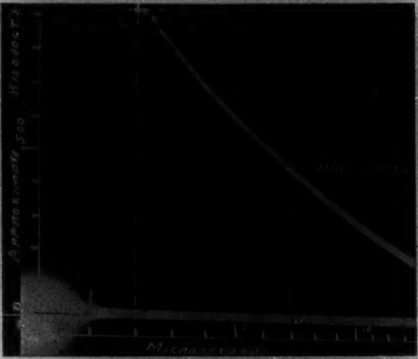
*A report prepared by the lightning and insulator subcommittee of the A.I.E.E. power transmission and distribution committee.

Lightning and insulator subcommittee: Philip Sporn, *chairman*; W. W. Lewis, J. J. Torok, J. T. Lusignan, K. A. Hawley, H. H. Spencer, I. W. Gross, H. L. Melvin.

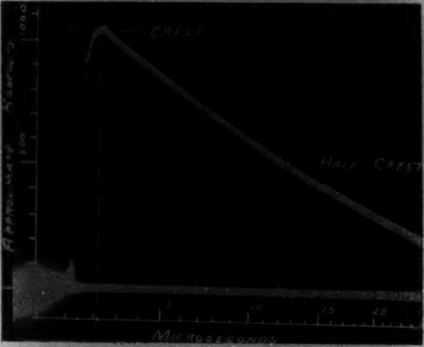
*Presented at the winter convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

Field records have shown lightning waves to have fronts and lengths varying over an extremely wide range; it is believed, however, that the 3 recommended wave shapes cover a range sufficiently broad to meet, as well as is practicable in the laboratory, the requirements for determining insulation breakdown characteristics for natural lightning. The committee does not recommend that every laboratory impulse test be conducted with all 3 waves, but that when test waves are being selected, preference be given to one or more of these 3 so that the results can be compared and used on a common basis. In choosing these 3 waves, consideration was given as to whether or not they could be produced satisfactorily and consistently in the various laboratories. Wave fronts shorter than one microsecond have been used in the past, but it was felt that one microsecond should be the established lower limit. The reason for this is that while satisfactory wave fronts of a fraction of a microsecond can be produced at the lower voltages, it is practically impossible to secure them at the upper voltage limits of some of the present-day lightning generators. The ability to impose a potential of several millions of volts upon a test piece and its lead from the lightning generator within a fraction of a microsecond without excessive and indiscernible oscillations can be questioned. The insertion of series resistance in the test circuit to check the oscillations results in lengthening the wave front to the order of a microsecond, and sometimes even longer. Because of the decreased damping effect of the high shunt resistance required for the longer waves greater series resistance is necessary to prevent oscillations on the front and crest of the wave. It is for these reasons that the 1½-μsec front was chosen for the 40-μsec wave.

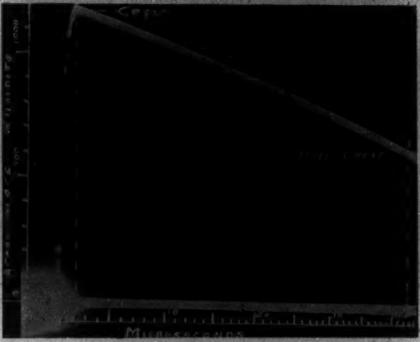
The wisdom of suppressing wave front oscillations in the manner indicated might be questioned by some, because in some cases lightning surges themselves may lack the proper circuit constants to eliminate oscillations on their fronts. In the laboratory, however, while it is essential to simulate lightning wave shapes as closely as possible, it is equally important that definite test waves be adopted which can be reproduced, measured, and recorded with reasonable accuracy. Not only are impulse waves with imposed oscillations of an appreciable magnitude difficult to duplicate consistently even on the same impulse generator, but also sphere gap measurements and oscillographic reproductions of such waves taken



1,000-kv 1 x 5-μsec wave



1,050-kv 1 x 10-μsec wave



1,200-kv 1½ x 40-μsec wave

These oscillograms have time to half crest voltage indicated from the crest, rather than from the zero point as recommended by the Committee

FIG. 1—OSCILLOGRAMS OF WAVES SIMILAR TO THE 3 RECOMMENDED WAVES, AS OBTAINED IN A TYPICAL LABORATORY

on the low voltage taps of potentiometers usually involve serious inaccuracies.

In recommending the 3 preferred test waves it has been necessary to compromise between the steepest and longest-tailed lightning waves so far observed on transmission lines, and the waves that can be obtained practically on insulation in a laboratory. That the recommended waves can be obtained in the laboratory is shown by actual oscillograms of impulse waves reproduced in Fig. 1. Similar waves have been obtained in other recognized laboratories. In Figs. 2, 3, and 4 are shown, in full lines, the 3 recommended test waves calculated from the circuit constants of the lightning generator. The dotted lines show the same 3 waves obtained by joining with straight lines the points actually specified in the definition of the waves.

Impulse wave shapes proposed or recommended by other A.I.E.E. committees also have been considered in an attempt to coordinate the several test waves in use. The transformer subcommittee of the electrical machinery committee has selected tentatively a 1½ x 40-μsec wave for impulse tests to be applied to transformers. (See progress report on *Impulse Testing on Commercial Transformers*, by Vogel and Montsinger, p. 409 of this issue.) Impulse waves recommended for lightning arrester testing by the lightning arrester subcommittee are defined both by rate of rise of the front and also by their ability to produce current through the arrester after the arrester comes into action. Such impulse waves cannot be used to give the desired information in insulator testing because: first, the voltage characteristics of the tail of the wave are not defined (tail of wave sparkover is an important factor in insulator testing); and second, it is impractical to obtain in the laboratory a constant rate of voltage rise, as the crest voltage of the test wave is altered successively in testing various types and sizes of insulators.

It is evident from the foregoing that the 3 preferred test waves recommended have been coordinated so far as is possible and practical with:

1. Natural lightning effects on transmission systems.
2. Reproducibility of these test waves in the laboratory.
3. Test waves proposed for impulse testing by other A.I.E.E. committees.

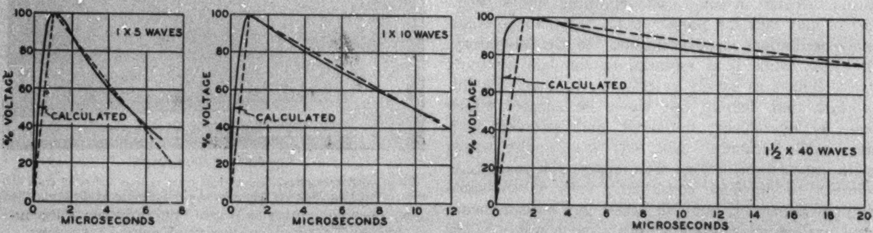
### TECHNIQUE AND PRECAUTIONS IN IMPULSE TESTING

Although the 3 wave shapes recommended are defined simply by front and tail characteristics, some difficulties may be met in producing them in the laboratory and in applying them to test work, if considerable care and precautions are not taken. The subject of impulse testing technique was discussed in 2 papers in 1932: *Characteristic of Surge Generators for Transformer Testing*, by Bellaschi, A.I.E.E. paper No. 32-87 and "Impulse Testing Technique," by Foust, Kuehni, and Rohats, *G.E. Review*, v. 35, p. 358, 1932. Two additional papers were presented at the 1933 A.I.E.E. winter convention: *Laboratory Measurement of Impulse Voltages*, by Dowell and Foust, page 537 of this issue; and *Measurement of High Surge Voltages*, by Bellaschi, page 544 of this issue. The lightning and insulator subcommittee commends the full and frank presentation of such discussions.

It is recognized that conditions under which the various laboratories must work are not at all identical, and that improvements constantly are being made in testing apparatus and methods. This committee, therefore, does not contemplate the standardization of test equipments, circuits, or methods. Rather, it is intended that the design and selection of testing equipment, the analysis of discharge-circuit current and voltage conditions, and the selection of test methods, be placed on such a basis as to leave no doubt that conditions of voltage application to the sample being tested are known thoroughly and are demonstrable. For this purpose the following recommendations are made:

### TESTING RECOMMENDATIONS

1. Use only testing equipments and circuit arrangements that can be analyzed readily as regards the location and amounts of capacitance, inductance, resistance, and conductance constants present, all of which have an appreciable effect on the shape of the voltage wave applied to the test specimen.
2. Measure with reasonable accuracy such circuit constants as indicated in item 1.
3. Calculate voltage wave shape at the sample under test.
4. Take cathode ray oscillograms of wave shapes applied to the sample under test.
5. Compare the calculated voltage waves with the waves obtained in oscillograms.



FIGS. 2, 3 AND 4.—THE 3 RECOMMENDED IMPULSE VOLTAGE WAVES AS CALCULATED FROM THE CONSTANTS OF THE LIGHTNING GENERATOR. DASH LINES HAVE BEEN DRAWN THROUGH THE POINTS SPECIFIED IN THE DEFINITION OF THE WAVES

6. Adopt such testing technique as is best suited to the testing equipment being used and the sample being tested.

7. Include with test results all details regarding each of the previous 6 items, such as will bear full evidence that testing conditions are thoroughly known and fully demonstrable.

8. Wherever possible, make impulse tests with both positive and negative applied voltage.

### MEASURING SPHERE GAP

The measuring sphere gap, which commonly is used as the primary standard for determining the applied impulse voltage, should be selected in accordance with A.I.E.E. STANDARD No. 4. These standards apply to spheres up to 750 mm in diameter and to rms voltages up to 900 kv. At present there are no agreed-upon standards for spheres larger than 750 mm, although in several laboratories such spheres are in use and higher voltages are being measured by reference to calibration curves from different sources. It is recommended that the appropriate Institute committee take steps to extend the sphere gap calibrations.

### STANDARD TEMPERATURE, PRESSURE, AND HUMIDITY

All test results obtained under prevailing temperatures, barometric pressure, and humidity conditions, should be corrected to the following standard conditions:

| | |
|---|---|
| Temperature | 77 deg F (25 deg C) |
| Barometric pressure | 29.9 in. (760 mm) of mercury |
| Humidity | That corresponding to a vapor pressure of 0.6085 in. (15.45 mm) of mercury (65% relative humidity at 77 deg F, and barometric pressure of 29.9 in.) |

Sphere gap and sparkover voltages should be corrected to standard atmospheric conditions of temperature and pressure by the use of the air density correction factors given in A.I.E.E. STANDARD No. 4. It is assumed that there is no humidity correction for sphere gaps.

The test piece flashover voltage should be corrected to standard atmospheric conditions of temperature and pressure by the use of the relative air density correction factors given in A.I.E.E. STANDARD No. 4. Although air density correction factors would be somewhat more accurate, such factors have not been established for the various types of insulators and gaps.

Humidity correction, based on vapor pressure as discussed in A.I.E.E. STANDARD No. 41, must be determined from data accumulated on different types of insulators and gaps. Since correction factors for humidity are not now generally available for impulse voltages, it is recommended that a record always be made of the existing humidity, so that later the data may be corrected to a standard humidity condition.

### TOLERANCES OF MEASUREMENTS

Since the practical application of impulse data on insulation involves, in most cases, the accuracy of the measurements, it is important that the possible and probable limits of this accuracy be known. It is recommended, therefore, that all impulse test data be accompanied by a statement of both the estimated possible and probable errors in magnitudes of voltage and time.

At present it is believed that discrepancies in the average sparkover voltage as obtained in different laboratories may be as great as 20 per cent on tests made with the short wave, and 5 per cent with the two longer waves; also in any one laboratory individual values vary ± 5 per cent from the average values. A better understanding and application of laboratory technique and test equipment promises, for the future, an appreciable reduction in these overall tolerances.

### PRACTICAL APPLICATION OF IMPULSE DATA

The purpose of obtaining flashover characteristics of any insulation is, of course, to determine its electrical strength. In the past the electrical strength of insulation has been judged by its 60-cycle flashover voltage. To-day it is recognized that lightning or impulse surges cause the greatest number of line flashovers; therefore, it is important to know the impulse flashover characteristic of the insulation.

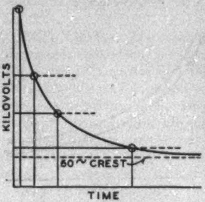


FIG. 5.—VOLT-TIME FLASHOVER CHARACTERISTIC OF INSULATION FOR A THEORETICAL SQUARE-FRONT FLAT-TOP WAVE

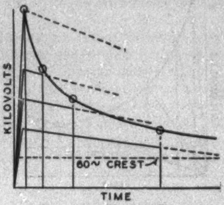

FIG. 6.—VOLT-TIME FLASHOVER CHARACTERISTIC OF INSULATION FOR A PRACTICAL SQUARE-FRONT FLAT-TOP WAVE

One of the chief uses of information on the impulse flashover of insulators is for comparison purposes in the choice of insulation for proper coordination. Exact impulse characteristics of the insulation must be known if proper levels of insulation are to be established. To coordinate insulation properly throughout the entire range of impulses which might appear in practise, it is necessary to know more than the flashover value of the insulation at one point of one particular impulse wave.

At present, there are several ways of obtaining a nearly complete picture of the impulse characteristics of insulation. One of the most desirable of these is by determining what may be called the volt-time characteristic of the insulator. Volt-time characteristic curves may be obtained by applying an impulse potential across the insulator and determining the time required for flashover. Succeeding applications of voltage are made with different crest voltages, the time to flashover being determined for each application. The crest value of impressed voltage and its corresponding time to flashover then is plotted as shown in Fig. 5.

While theoretically this method of obtaining volt-time curves is highly desirable, it is impractical because in any laboratory where cost of equipment is a factor, it is impossible to obtain a square front flat top wave. However, the type of curve shown in Fig. 5, may be approximated by impulse waves, such as those shown in Figs. 6 and 7. In Fig. 6, a single wave shape is used at different amplitudes and all breakdowns are on the tail of the wave. In Fig. 7, all breakdowns are taken on uniformly rising wave fronts, the front being changed for each voltage application.

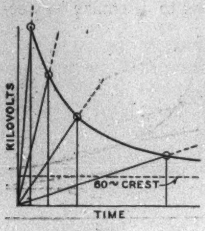

Fig. 7. Volt-Time Flashover Characteristic of Insulation With Breakdown on Front of Wave

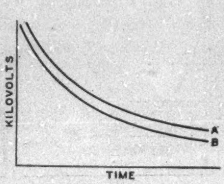

Fig. 8—Typical Flashover Characteristics of 2 Coordinated Insulating Members

Another way of obtaining impulse characteristics of an insulator over wide ranges of time is to use waves of different shapes and determine by repeated application the minimum voltage which will just cause sparkover. This is called the minimum wave, 50-per cent sparkover method, that is, the minimum voltage which on being applied to the insulator, will cause sparkover half of the time. This method could well employ the 3 test waves recommended in this report, and does not require the continuous use of an oscillograph. The method becomes more accurate as the number of waves is increased.

It must be recognized that characteristic curves obtained by the 2 methods described are not comparable; that is, data obtained with the 50-per cent sparkover method will not have the same characteristics as data obtained with the methods illustrated in Figs. 6 and 7. At present, laboratory data available are insufficient to allow greater significance to be attached to one of these methods rather than to any other. Sufficient data should be obtained by the different methods to permit definite conclusions to be drawn as to the value of each method.

A survey of data already accumulated indicates that considerable information is available regarding the impulse flashover characteristics of various types and forms of insulation. However, a large part of the data has been obtained either by methods now obsolete or on a basis which would not be comparable with the methods outlined here, and particularly on a basis such that data obtained in different laboratories are not comparable. Only in the past year or so can data published by the more important laboratories be used for insulation coordination, and then only on that particular basis on which the data have been secured.

For the foregoing reasons it is essential that impulse data be obtained on some fixed basis for apparatus such as insulators, bushings, gaps, and other insulating members. This fixed basis may well take the form of a volt-time curve such as those illustrated in Figs. 6 and 7. However, it is clear that the obtaining of comparable data on these bases requires the use of a definite wave or group of waves.

Since both positive and negative waves are found on transmission lines, it is important in the laboratory to obtain impulse data for both polarities. Much of the earlier impulse data have been obtained without particular regard to polarity; consequently, the averaged values may lie between the positive and negative flashover values of that insulation. More recently testing has been done on a basis in which only one wave is used, either the positive or the negative. Since it was recognized that the positive impulse sparkover voltages were lower than the negative, it was decided to obtain the impulse information by using principally the positive wave. For complete and reliable coordination, however, it is necessary to have both positive and negative volt-time curves of all of the insulation involved.

For comparative purposes throughout a wide range of possible impulse voltages found in practise, the volt-time characteristics of an insulator give the most complete and therefore the most desirable information. By the use of these curves the relative behavior of 2 pieces of insulation subjected to impulse voltages can be predicted. For example, one form of insulator may have a characteristic curve as shown in curve *B* of Fig. 8, and a bushing may have the curve *A* characteristic; if the insulator and bushing are connected in parallel, the insulator will flash over, on the application of an impulse voltage, rather than the bushing. Predicting insulation breakdown on this basis is the ultimate aim of impulse testing. By this method the location of flashover of insulation can be controlled.

Coordination of insulation on the above basis may be expected to result in advantages as follows:

1. Protection of expensive and important apparatus against the effects of lightning should be more complete than at present, even where lightning arresters now are used.
2. Greater economy of system design should be possible without the danger of subjecting valuable apparatus to breakdown from lightning.
3. Lower maintenance costs on station apparatus subject to the effects of lightning may be expected, since it should be possible to prevent destructive impulse voltages from reaching that apparatus.
4. Electric service as a whole should be improved, since by insulation coordination, it should be possible to control the location of lightning flashover on the system so as to result in a minimum of damage and service interruption.

## CONCLUSIONS

Important points brought out in this report and recommendations made by the lightning and insulator subcommittee may be summarized as follows:

1. Impulse voltage characteristic data on insulation which have been obtained in various laboratories up to the present time, have been on such widely different bases that the effective use of this data has been almost impossible.
2. The committee recommends 3 preferred impulse test waves, 1 x 5, 1 x 10, and 1½ x 40 μsec, the use of which in all laboratories should result in comparable data being obtained on impulse characteristics of insulation.
3. That these recommended test waves actually can be produced in practise is demonstrated by the group of laboratory test waves, oscillograms of which are reproduced in this report.
4. To insure insulation actually being subjected in the laboratory to impulse voltages of known characteristics, a group of general recommendations for laboratory procedure have been made by the committee.
5. It is recommended that, wherever possible, oscillograms of the actual impulse wave or waves applied to insulation be obtained at the time of test.
6. For the intelligent application of impulse data in actual practise, tolerances or accuracies obtainable in laboratory measurements should be taken into account. Failure to do so may affect greatly the successful coordination of insulation on an electric system.
7. Complete information on the impulse characteristics of all insulating members of an electric system is necessary for proper coordination of insulation. This information is desirable in the form of volt-time curves, types of which are illustrated in this report.

It is hoped that the recommendations made in this report will offer a basis for more rapidly advancing the art of satisfactory insulation coordination on the impulse basis so that all possible economies in the design of electric systems and improvement in the service supplied by these systems may be actually realized.

## Discussion

**A. O. Austin:** There are so many factors involved which affect the flashover values obtained under an impulse that the committee has done much in obtaining a fairly uniform agreement as to results from most of the laboratories. The difference in equipment and the difficulty of obtaining uniformity with certain types of waves make it necessary that comparisons be made with waves which can be produced and which will give fairly uniform results in the various laboratories. Unless this can be done of course comparisons cannot be made with any degree of certainty. However, it must be recognized that in operation a direct hit usually results in a very steep front in the immediate vicinity. Unfortunately impulses of this type are attended with oscillations and are more or less difficult to analyze and compare.

Many systems probably do not have conditions imposed upon the equipment having any steeper fronts than the waves proposed. However, it will be found that protective apparatus must take into account waves of steeper front if protection is to be provided for direct hits in the immediate vicinity. A protecting gap which will provide protection to a bushing, bus insulator or other piece of insulation with wave fronts of 1 to 1½ microseconds may have to be very materially reduced in order to provide protection for a direct hit in which the wave fronts may be very much less. In providing protecting equipment the flashover values and time lags may be quite different for the positive and negative impulses, hence the protecting gap should be adjustable so as to take this into account if protection is to be provided with a minimum of tripouts.

It has been more or less common practise to equip bushings so that a discharge point or electrode could be attached to the top for reducing the flashover voltage on positive impulse and a discharge point applied at the flange to control the flashover under negative impulse. A protecting gap which can be adjusted not only to change the time lag but to regulate the time lag and flashover voltage for negative and positive impulses was presented in a paper before the A.I.E.E. at the Milwaukee meeting in 1932[1].

**F. D. Fielder:** The committee has recommended two general schemes for laboratory testing: the use of minimum flashovers on three different waves, and the use of time lag curves obtained with a long wave. It is noteworthy that besides showing insulation characteristics more completely, the time lag curve method is becoming more generally used. It seems logical that the use of three different shapes of waves be eliminated to conserve laboratory time, especially since it is possible that minimum flashover values with waves of different tails can be obtained from specific points of the more complete time lag curves. It is noted that volt-time curves are described for cases where the breakdown occurs on the rise of the wave. Those with laboratory experience will agree that this type of test is impractical at very high voltages, because of insulation difficulties with high voltage inductances. This method is not widely used at the present time for this reason.

We neither approve nor care to accept the enumerated testing recommendations. Such a method is laborious, and certainly not conducive to precise impulse measurements. Calculations may have certain value, but when they have been once used to show the proper operation of the circuits, it seems needless to repeat them for every change of apparatus. In addition there is some question as to how rigorous methods of calculation should be.

We also do not agree with the proposed use of the sphere gap as a primary standard. Although A.I.E.E. Standard No. 4 gives curves for spheres up to 750 mm, these curves apply only for commercial voltages, and they have not been experimentally checked for surges. Careful investigation shows that the curves do not check each other in parallel surge tests, and that positive and negative surge calibration curves differ.

Peek has clearly defined the ½/5 wave as meaning a ½ microsecond front and a 5 microsecond tail[2]. We also have used this designation for a number of years. There is no apparent advantage in changing. The shorter wave resulting from the definition proposed by the committee will mean greater surge generator regulation. Also with this new wave, apparatus will have higher flashover voltages. Both factors decrease the apparatus testing range of a given surge generator. This point is very important when it is necessary to use several hundred ohms series resistance to secure a reasonably smooth wave. For these reasons we do not approve of the change.

---

[1] *An Improved Type of Limiting Gap for Protecting Station Apparatus* by A. O. Austin, A.I.E.E. TRANS., Sept. 1932, p. 676

[2] A.I.E.E. TRANS., October, 1930, p. 1460

The most pressing question regarding surge tests is the disagreement in reported results from the different laboratories. It is believed that these differences should be the object of immediate study. Rather than devise test codes and procedures and schemes for collecting data, there should be further concentrated study of the fundamentals of the problem.

**C. L. Fortescue:** There is need for comment on the recommendations for impulse voltage testing put forward by the Lightning and Insulator Subcommittee. The three standard waves chosen are satisfactory for laboratory testing and are fairly representative of types of waves that may be expected to enter a substation connected with transmission lines. Where it is desired to find out the effect of very steep waves on insulators, gaps, and so forth, this can readily be done using a powerful surge generator by removing the damping resistors and applying the full value of the surge to the insulator string in which case flashover will take place on the front of the wave at a low time lag and high impulse factor. Here the slope of the wave is of primary importance. The effect of oscillations which appear at the crest and tail of the wave are eliminated. The writer comments as follows on the proposed testing recommendations: The calculation of the shape of the voltage wave applied to the test specimen always is worth while but it should be recognized that even for the simplest circuit the solution at best is approximate. A rigorous solution is extremely difficult and the time required to carry it out would make it impracticable. In the writer's opinion the cathode ray oscillogram used in connection with a reliable voltage divider is the best method of measuring the impulse voltage required to break down the piece under test and the time lag. There is some question as to the calibration of the sphere gap, except for gap settings less than the radius of the sphere.

The writer regards the impulse time lag curves of insulators and spark gaps as giving their fundamental breakdown characteristics under surge conditions and has found that these curves can be used very effectively in determining the length of insulator strings, tower clearances, and ground wire to line wire spacings for the types of waves encountered when ground wires or towers are struck by lightning. It would be desirable to obtain these impulse time lag curves by using a wave more nearly approximating a perpendicular flat topped wave. If the importance of the volt-time lag curve had been recognized at the start, means might have been developed to obtain a more desirable wave for this purpose. However, the 1½-40 wave gives good practical results though the impulse ratios at the shorter time lags show up high since breakdown takes place at the front of the wave. It is not difficult to make allowance for this, at least for such approximate calculations as are used in estimating the protection level of transmission lines. It is important that the laboratories should be encouraged to develop their technique in obtaining voltage time lag characteristics of insulators and spark gaps for these are fundamental data.

The data obtained by the several laboratories are now fairly complete. A good part of these data secured by one of the laboratories is presented in the paper by Messrs. Montsinger, Lloyd and Clem (see page 417). An examination of these data will show, compared to Westinghouse data, that the correspondence is very close on the long wave impulse time lag curves but not so good on the short wave impulse time lag characteristics. It seems that the long wave testing gives less chance for variation due to technical differences in the various laboratories. In my opinion impulse time lag characteristics will give sufficient data for practical use in coordination of insulation.

**C. M. Foust:** In spite of dealing with a rather difficult subject the committee has produced a report which is factually sound, comprehensive and forward looking. In submitting a word of caution regarding volt-time breakdown curves, the writer believes that the so-called minimum wave flashover volt-time curve as shown in Fig. 6 has been credited with a wide significance that cannot be demonstrated by existing data regarding practical operating conditions or the mechanism of insulation breakdown. Coordination of insulations on the basis of volt-time data from wave tail flashovers should be accepted as applying only to field conditions where the incoming waves are of just sufficient voltage amplitude to produce wave tail flashover. The same time-voltage relationship does not hold for other conditions of voltage application such as wave front breakdown as shown in Fig. 7.

Apparently it is necessary to consider two general factors when tests are being planned for the purpose of working out insulation coordination. The first of these factors has to do with wave shapes found in operation, on which shapes coordination is necessary, and the second with the mechanism of breakdown of the insulations being coordinated.

Regarding waves in power circuits, available data indicate that a wide range of shapes are present. Steep front waves of high voltage amplitude giving breakdown on the wave front, as well as low voltage sloping front waves, have been recorded; in each particular case where coordination on the front or tail should be considered. Also it may be desirous in some cases to coordinate on all three recommended waves allowing breakdown to come on the front, crest or tail as the mechanism of breakdown of the insulation determines.

The second general factor of importance, mechanism of insulation breakdown, has not received the attention it should. Consider for instance the case of two insulations each having about the same minimum wave crest voltage breakdown, each having definite impulse ratios but one breaking down on the wave tail and one on the wave crest. This is not an imaginary circumstance. In general insulators flashing over through long arcs, or breakdown over solid insulation surfaces where long creepage streamers are formed give wave tail breakdown. In this case the usual minimum wave tail breakdown volt-time curve is obtainable. But through breakdown of solid insulation, short arcs through oil, vacuum or other insulations in general do not give wave tail breakdown although they do have high impulse ratios. Here the minimum wave, tail breakdown, volt-time curve is *not* obtainable.

The long arc breakdown giving wave tail flashover should be regarded as a volt-time phenomenon somewhat on the following basis: The streamer bridging between the two electrodes grows in length at definite rates depending upon the overvoltage applied. With a flat topped wave adjusted to critical breakdown value the streamer tip velocity is low and the large time element required for its formation therefore easily measurable. With a decreasing voltage on a wave such as the (1½-40) a higher crest voltage is required than for the square topped wave and the time elements are shortened somewhat although still of appreciable magnitude to permit good measurement. Flashover in this case is a race between the decreasing velocity of the streamer tip and the falling voltage behind the streamer.

Obviously when insulations having such radically different mechanisms of breakdown are to be coordinated a careful study of the nature of breakdown is required if great confidence is to be had in the arrangement decided upon.

Factual matter such as touched on briefly in this discussion must carefully be considered for future work. Good progress will be achieved by careful planning of investigational work in the field and in the laboratory. This planning must be directed toward the securing of information which will inspire confidence in the significance of laboratory tests. Large expenditures directed solely toward the accumulation of more of what this committee rightfully classifies as "obsolete data" are not desirable. Careful scientific research work directed toward a clarification of the problem at hand is most necessary.

**K. A. Hawley:** It may be well to point out just why it is desirable to make impulse tests with both positive and negative waves. If there were in all cases a constant percentage of difference between the positive and the negative flashover values then a measurement with one polarity would be all that is required for coordination purposes. Actually the percentage of difference between positive and negative values varies considerably with different insulators. The limits of this variation with the usual commercial insulators and gaps is not definitely known at this date. There are some known cases, however, in which the negative wave flashover of one insulator has been more than 30 per cent higher than the positive wave flashover, while the flashover value of the coordinating gap has been almost the same for both positive and negative waves. Obviously in such cases if the flashover measurements for coordination had been made using a negative wave only, then satisfactory coordination would not be obtained for positive waves. It is perfectly conceivable that in some other cases coordination established using only a positive wave may not be obtained when a negative wave is used.

In connection with Fig. 8 it should be noted that these curves need not always be parallel as shown. In fact in many cases there is a great difference in the slope of the volt-time curves for different insulators and gaps. If curve *B* happened to be steeper than curve *A* and crossed curve *A*, then although satisfactory coordination would be indicated by tests using the "minimum wave" or "50 per cent sparkover" method still when higher voltages were applied the coordination would be destroyed. Since the maximum expected wave on a transmission line usually will be considerably above the flashover value of the insulators involved in the coordination, it is apparent that some knowledge of the volt-time curves is essential.

**K. B. McEachron:** From the point of view of protecting insulation from flashover due to direct strokes it is necessary to give consideration to the front of the wave flashover. A very large proportion of direct strokes apparently have sufficient potential available to flash over the usual insulation strengths on the front of the wave. The tail of the resulting traveling wave will depend upon the form of the current wave of the direct stroke and the tower footing resistance.

The present proposed standards for testing lightning arresters referred to in the committee report were intended to furnish data from which comparisons of arresters could be made, but not necessarily to represent performance in service.

It is possible to make tests on lightning arresters using the three waves proposed in the report, but to obtain appropriate current waves the test should be made on a transmission line. Under such a condition the current is related to the potential of the traveling wave and the rate of current rise is the same rate which would have been obtained with natural lightning of the same wave shape. On the transmission line when the potential is a maximum the current is also a maximum, but in the laboratory this relationship is in general not readily obtainable. Since the test on a transmission line is expensive, the lightning arrester subcommittee did not propose its use, although the day may come when it will be feasible.

Oscillograms are available showing the performance on thyrite arresters on a transmission line of the Consumers Power Company taken in 1930. Such records show the exact performance of the arresters under conditions obtaining in service.

Lightning arresters must operate on the front of the wave and therefore the rate of rise is important in determining the potential at which the arrester begins to carry current with different wave fronts applied. Once the arrester becomes conducting, the only effect of the tail of the wave is to determine the magnitude and form of the current wave through the arrester.

When testing insulators only the potential wave is of importance, which accounts for the difference between the arrester proposed standard tests and those suggested by the committee.

**H. K. Sels:** Referring to the subcommittee's recommendation for impulse voltage testing, Mr. Alger has called attention to the limitations of such standard waves in the testing of rotating machinery which the writer believes may also be true of other equipment, particularly lightning arresters. With lightning arresters, it is desirable to have them discharge as soon as possible under impulse voltages and maintain as low a terminal voltage as possible while the discharge is taking place. Therefore, while initially voltage conditions prevail, after the discharge starts, the current conditions are the criterion for determining the resulting arrester voltage. Hence, a different sort of specifications than those proposed are necessary.

Two years ago, the subcommittee on lightning arresters recommended impulse waves for testing station type arresters above 15 kv with a voltage rise of 100 kv per microsecond per 11.5 kv of arrester rating and after the beginning of discharge with a current rise of 150 amperes per microsecond to a crest of 1,500 amperes. Other variations in the wave are also given for lower voltage ratings and line type arresters. It is believed that with the present limitations in test equipment, these tests are adequate for comparative purposes, although no indication is given of the protective capabilities of the arrester to protect equipment under service conditions. Whether traveling wave conditions with both voltage and current waves also are necessary in the testing of other equipment is a problem which should be considered by the subcommittee.

**F. J. Vogel:** The report is very valuable, furnishing a standardization of the test waves and an interpretation of the test results. However, the specifications for the procedure of tests in the laboratory, under the heading "Testing Recommendations," are unnecessarily complicated. In a properly standardized laboratory, it should be possible to analyze once and for all the performance of the surge generator and to demonstrate the accuracy of the cathode ray oscillograph and divider. For example, the work done in Sharon in analyzing the performance of the surge generator was presented to the Institute at Cleveland in June, 1932, by Mr. P. L. Bellaschi[3] and furnished the first known published analysis of a surge generator circuit to take account of the stray generator and load capacity. The work done at Sharon in calibrating the cathode ray oscillograph and its dividers is given in the paper by Mr. P. L. Bellaschi on page 544 of this issue. After this analysis and calibration have once been accomplished, it would seem that the use of such a calibrated system is in no way different in principle from the use of the more common indicating meter. In this case, there is no need of calibrating the meter for each individual test, but occasional checks are all that is required.

**P. L. Bellaschi:** Each of the main items treated in this report could well be made a subject of profitable discussion and critique. The question of measuring sphere gaps is particularly pertinent for discussion from a fundamental standpoint.

The subcommittee definitely accepts the present standard calibration curves of sphere gaps (A.I.E.E. Standard No. 4) for surge voltage measurement, and on this basis it considers the sphere gap as a primary standard for surge voltage measurement. It should be noted that these calibration curves were established for measurement of voltage at power frequencies. It is a simple matter to show that these calibration curves are incorrect for measurement of surge voltages. The issue of the matter is this: In the application of the sphere gap to surge voltage measurement, there is no fundamental basis to justify its use as a primary standard; in truth, it is a secondary standard. In surge voltage measurement, the sphere gap should therefore be calibrated, or better still, a resistance potentiometer used directly.

**Philip Sporn:** Since any group of impulse voltage test waves must of necessity be a compromise based on actual lightning waves on transmission lines, theoretical calculated waves, and waves which actually it is possible to produce in a practical laboratory, it is particularly gratifying to note from the discussions that the three waves recommended by the committee have generally been accepted not only as practical but also as adequately covering any reasonably possible voltage conditions which may be met with in practise.

---

[3] *Characteristics of Surge Generators*, A. I. E. E. TRANS., December, 1932, p. 936.

Now that a uniform yardstick (that is, the three preferred test waves) has been established, it is believed that impulse testing has taken a decided step forward. There still remain, however, several problems in the production, application, and use of data secured by these test waves.

Mr. Fielder seems to have the impression that the committee has recommended obtaining impulse data according to two general schemes: first, obtaining minimum flashover with three different waves and, second, obtaining time lag data with the long wave. It should clearly be pointed out, however, that the committee at the present time has not made any recommendations on the type of impulse data to be obtained to the exclusion of any other type. As a matter of fact, the members of the committee at the present time are not in agreement that any one of the typical curves of impulse characteristics of insulation given in the paper will supply enough information properly to coordinate insulation strengths in a transmission system. Some members favor one type of voltage time lag curve and some another type; and it may be that the necessary complete picture of the impulse strength of insulation will be shown only when data are secured with all the different waves used in all the different manners indicated in the paper.

Mr. Fielder also is under the impression that there is no apparent advantage in measuring all times of impulse waves from the zero point of the wave. There are, in our opinion, however, two distinct advantages in measuring time from the zero point of the wave. The first is that there is less confusion in indicating time from a fixed point, one, such as the origin of the wave rather than from a reference point which is subject to some time variation as is the case with the crest of an impulse wave with varying load conditions on the generator. The second advantage is that since in the calculation of impulse wave shapes, all times are computed from the origin of the wave, there is less chance of error and misunderstanding if the start of the wave is used as a reference point. This matter was gone into thoroughly in the committee meetings and it was felt that every advantage was in favor of measuring time in all cases from the zero point of the wave rather than from the crest.

Another point on which discussion was raised was that of using the sphere gap as a measuring device for indicating the crest value of impulse waves. It is felt that it is much better, with our present knowledge of voltage measuring devices, to measure impulse waves with a standard such as the sphere gap rather than some other device which has not yet been thoroughly tested, proved, and accepted as a standard. It is readily appreciated, however, that with continued use, and a better understanding of factors influencing the ratio of resistance potentiometers they may well take their place along with the sphere gap or possibly replace it as a measuring device in impulse testing. Until such time, however, the evidence is not very conclusive that anything is to be gained by dropping the sphere gap as a standard of voltage measurement.

The discussions by Messrs. McEachron and Sels referring to the type or voltage waves recommended by the Lightning Arrester Committee for testing lightning arresters seemed to show quite clearly that the testing of lightning arresters and insulators cannot be coordinated by the use of one common impulse test wave at the present time, on account of practical difficulties in test circuits. Since the function of a lightning arrester is to get into action as soon as an excessive voltage appears on the line, and further to discharge the impulse current while holding this voltage to a safe value, it appears that any test wave for a lightning arrester should logically be based on the rate of voltage rise of the lightning wave and the ability of the wave to supply current through the arrester. The shape of the tail of the wave, therefore, is of importance only as it affects the supply of current to the arrester.

In the case of insulator testing, however, it is the voltage time characteristic of the wave throughout its entire duration which alters the insulation strength of the insulator. The current in the test wave does not affect the impulse performance of the insulator. It seems readily apparent, therefore, that any attempt to use the same impulse waves for testing lightning arresters and insulators will result only in a restriction of our knowledge of arrester performance and the ability of insulation to withstand flashover.

Mr. Hawley's discussion brings out clearly why it is necessary, in obtaining a more nearly complete picture of insulation strength, to test with both positive and negative impulse waves. Information on both polarity should, of course, be obtained for the maximum benefits to be secured in obtaining impulse characteristics of insulators. The excellent work that has been done during the past few years in analyzing the fundamentals of impulse testing in the laboratories has done much to place impulse testing on a more sound and rational basis. While there are still some points of disagreement, it is believed that if the various laboratories continue their efforts, that a common basis for conducting tests and reporting data can be reached which will be of great benefit to all who have occasion to deal with problems involving impulse strength and characteristics of insulation in all its varied forms.

# Lightning Investigation on Transmission Lines—III

BY W. W. LEWIS*
Member, A.I.E.E.
and
C. M. FOUST*
Member, A.I.E.E

***Synopsis.**—The field data for 1931 and 1932 are reviewed, with especial reference to lightning stroke currents. When direct strokes take place to towers or ground wires, flashover occurs if the product of current and tower footing resistance is higher than the flashover strength of the insulators. Flashover seldom occurs if ground wires are present and the towers have low footing resistance.*

*Three years' records on four systems indicate tower currents varying from 1,000 to 150,000 amperes. Tripouts correlate almost exclusively with high tower leg currents of negative polarity, that is, the tower top is negative with respect to the base. This indicates that the severe lightning strokes come from negatively charged clouds. A great amount of experimental data, relating to flashover between electrodes of dissimilar shapes, are shown to be in accord with these field observations.*

## INTRODUCTION

THIS paper is the fourth of a series of A.I.E.E. papers by the same authors, giving the results of a lightning investigation conducted on a number of power systems, through the cooperation of the power companies and the General Electric Company. The previous papers[1] summarize the results for the years 1926 to 1930 inclusive. Certain theories as to the mechanism of the lightning stroke and the effect of polarity have been presented.[2]

The present paper will bring the information up-to-date and further discuss the theories of the lightning stroke mechanism.

The investigation was continued in 1931 and 1932 on the Pennsylvania Power and Light Company's 220-kv Wallenpaupack-Siegfried line, the Ohio Power Company's 132-kv Philo-Canton line and the Atlantic City Electric Company's 66-kv Deepwater-Pleasantville line, all of which have been described in previous papers.[3]

Work was started in 1932 on the 132-kv Glenlyn-Roanoke line of the Appalachian Electric Company. This is a double-circuit line, 65 miles long, similar in construction to the Philo-Canton line. Three areas on this line, which had been subjected to numerous flashovers in the years 1927 to 1931, inclusive, were selected for the investigation. These areas are designated: towers 6 to 22, inclusive, Roanoke end, towers 50 to 69, inclusive, Roanoke end, and towers 8 to 28, inclusive, Glenlyn end.

During 1931 and 1932, work with the cathode ray oscillograph was discontinued. Data were secured with the following instruments: *magnetic oscillograph, surge voltage recorder, severity meter, lightning stroke recorder* and *surge indicator.* A new instrument, the *surge crest ammeter,*[4] was introduced on a limited scale late in 1932, but practically no data were obtained with it in the time available.

A number of "lightning rod" installations were erected on each of the four lines under investigation. On the 220-kv line these consisted of iron pipe extending 30 feet above the top of the tower. On the 132-kv lines a copper conductor was used, extending 10 feet above the top of the tower. The pipe or conductor was connected to the tower through a 0.15-ohm resistance, shunted by a lightning stroke recorder.

The ground wires at the towers equipped with lightning rods were insulated from the tower and connected to the tower through a 0.3-ohm resistance, shunted by a lightning stroke recorder.

The purpose of the lightning rod instruments and ground wire instruments, in connection with the instruments on the legs of the towers, was to differentiate between the total stroke current and that flowing in the ground wires and in the tower itself.

severity, tripouts, flashovers and the effect of ground wires. An effort has been made to formulate a rational theory of the mechanism of direct strokes.

### RELATION OF LINE TRIPOUT TO LIGHTNING STROKE CURRENT, TOWER FOOTING RESISTANCE AND OVERHEAD GROUND WIRES

*Wallenpaupack-Siegfried Line.* For several years efforts have been made to determine values of current in tower legs by means of the lightning stroke recorder.

In 1930, during the part of the season in which instruments were in service, records of 18 strokes were obtained, which were all interpreted as due to direct strokes. Nine of the ten strokes associated with tripout took place on the section of line not equipped with overhead ground wires; while seven of the eight strokes not associated with tripout took place on the section equipped with overhead ground wires or diverter wires.

Current—2,000 to 25,000 amp

In 1931 records were obtained of 53 strokes. Of these, 19 were accompanied by tripout and 34 were not accompanied by tripout.

In Table I are listed for these 53 strokes the product of tower current times tower footing resistance times $10^{-3}$, the product being proportional to kilovolts. The values used for resistance are the measured values for tower footings, with tower footing grounding cables or counterpoises, but without taking into account the effect of overhead ground wires.

In 1932, records were obtained of 33 strokes, of which 11 were accompanied by tripout and 22 not accompanied by tripout. In Table II are listed the product of tower current times tower footing resistance times $10^{-3}$ for the year 1932.

The records are usually grouped in several adjacent towers, all probably due to one stroke. In each group there is usually one high current reading and a number of smaller ones. In these tables are included only the maximum product for each group, as it is probable that this is the product which is of importance in connection with flashover.

It will be noted from these tables that a much greater percentage of the products are high for the records accompanied by tripout than for those not accompanied by tripout.

In Table III are summarized the lightning stroke recorder records for the three years, with particular reference to their location with respect to overhead ground wires.

It will be noted from this table that under the heading *Accompanied by Tripout,* from 80 to 100 per cent of the records were obtained on the section without overhead ground wires. The total number of records in the section without overhead ground wires varied from 52 to 68 per cent of the total for the whole line, which corresponds, roughly, with the length of the section without overhead ground wires, which is 57 per cent of the total length.

In other words, although the strokes were fairly well distributed over the whole line, the strokes causing tripout were concentrated on the section without overhead ground wires.

The data secured during these three years show conclusively the beneficial effect of overhead ground wires in preventing flashover and tripout.

On the section of the Wallenpaupack-Siegfried line equipped with overhead ground wires and counterpoise, tower WT-11-4 to tower WT-14-1 (14 towers in all), the flashed insulator assemblies for the years 1926 to 1932 were as follows (the counterpoise was in service during 1929 and subsequent years):

| Year | | Flashed insulator assemblies |
|---|---|---|
| 1926 | No overhead ground wires | 6 |
| 1927 | Ground wires installed | 9 |
| 1928 | Ground wires in service | 14 |
| 1929 | Counterpoise installed | 0 |
| 1930 | Ground wires and counterpoise in service | 0 |
| 1931 | Ground wires and counterpoise in service | 0 |
| 1932 | Ground wires and counterpoise in service | 0 |

It is apparent that to be really effective the ground wires must be supplemented by low tower footing resistance.

*Philo-Canton Line.* In 1931, records were obtained with the lightning stroke recorder of 25 strokes, involving 1 to 13 towers in each stroke. The tower current values varied from 2,000 to 80,000 amperes. All of the readings were negative, except those discussed in the following paragraph.

On June 26th, a chestnut tree, located 150 ft west of mid-span, between towers 174 and 175, was struck. Currents of 6,000 amperes positive were recorded at both towers 174 and 175. There was no indication of flashover and no tripout.

There were 7 tripouts on this line, of which 4 were due to flashover in the area covered by lightning stroke recorders (about 22 miles out of 73 miles total). Records were obtained of tower current in each of the four cases. The product of tower current times tower footing resistance gave values of indicated voltage much lower than the assigned flashover values in these four cases. The suggestion has been made that direct stroke to the conductor took place in these cases (it will be remembered that this is a double circuit line with one ground wire).

TABLE III—SUMMARY OF LIGHTNING STROKE RECORDER RECORDS WALLENPAUPACK-SIEGFRIED 220-KV LINE

| | 1930 | | 1931 | | 1932 | |
|---|---|---|---|---|---|---|
| | Ground wires | No ground wires | Ground wires | No ground wires | Ground wires | No ground wires |
| Accompanied by tripout | 1 | 9 | 0 | 19 | 2 | 9 |
| Not accompanied by tripout | 7 | 1 | 17 | 17 | 14 | 8 |
| | 8 | 10 | 17 | 36 | 16 | 17 |

Assuming that tower currents of 10,000 amperes or more were due to direct strokes, then 15 of the 25 groups of records would be classed as direct strokes and the remaining 10 may have been produced by direct or induced strokes.

Of the 15 groups of records classed as direct strokes, 4 correlated with line tripout. The remaining 11 groups were not accompanied by line tripout.

Of the 7 tripouts experienced in 1931, 5 involved both circuits of the double-circuit line and 2 involved only 1 circuit.

In 1932, records were obtained with the lightning stroke recorder of nine strokes, involving 2 to 12 towers in each stroke. Maximum tower current values varied from 3,500 to 20,000 amperes. All strokes were negative.

*Deepwater-Pleasantville Line.* In 1931, readings were obtained with the lightning stroke recorder in the case of 5 strokes, involving from 1 to 6 towers per stroke. Maximum tower currents varied from 2,000 to 113,000 amperes. All readings were negative.

There were 6 tripouts, of which only 1 correlated with lightning stroke recorder readings (in the other cases there were no lightning stroke recorders near the point of flashover). In the case which correlated (stroke No. 2) there was a reading of 113,000 amperes at tower 70, and small readings up to 7,000 amperes in 5 adjacent towers. The product of current times tower footing resistance times $10^{-3}$ at tower 70 was about 4,000 kv. Surge indicators operated on all three phases of circuit 2 at tower 70. Circuit 2 tripped out at both ends.

Two of the 6 tripouts involved both circuits and 4 involved only 1 circuit.

In 1932, only 2 strokes were recorded by the lightning stroke recorder. These involved 2 and 4 towers, respectively. Maximum tower currents recorded were 3,500 and 4,500 amperes. Both strokes were negative.

*Glenlyn-Roanoke Line.* Only one year's records are available on this line.

In 1932, eight readings were obtained with the lightning stroke recorder, involving from 2 to 4 towers per stroke. Maximum tower currents varied from 1,000 to 108,000 amperes. All strokes were negative.

## PROTECTION OF TRANSMISSION LINES BY OVERHEAD GROUND WIRES

*Induced Strokes.* Protection from induced strokes is best accomplished by means of overhead ground wires. Two ground wires placed directly above the conductors in vertical configuration or placed above and between the conductors in horizontal arrangement are usually sufficient for all practical purposes. The ground wires are placed above the conductors, a distance of 10 to 20 ft in the average case. Such an arrangement will reduce the induced voltage 50 to 70 per cent.[5]

The material of the ground wire is not important from the lightning standpoint, but for other reasons high conductivity ground wires are preferable. Tower footing resistances up to 75 or 100 ohms are tolerable.

*Direct Strokes.* For direct strokes, theoretical analysis indicates that the ground wires should be placed so that the conductors to be protected fall within a triangle formed by the ground wire as the apex and a base line on the ground equal to two or three times the height of the ground wire above ground. It is also required that the distance between the ground wire and conductors at mid-span is sufficient to withstand the full potential built up between them until this potential has had a chance to be relieved by waves traveling from the point of contact of the stroke to the ground via the towers. Such considerations call for ground wires 30 to 50 ft above the conductors.[5,6]

In practise, it has been found that conventional ground wires (placed as for induced strokes—10 to 25 ft above the conductors) will prevent flashover of the transmission line insulation, providing the insulation is reasonably strong and providing the resistance between the top of tower and ground is low. The larger part of this resistance is in the tower footing itself.

If the line insulation flashes over due to lightning, there may be no tripout, provided the ratio of the 60-cycle flashover of the line insulation to the circuit voltage is sufficiently high.

The following table gives the number of insulator units and tower footing resistances of steel tower lines with overhead ground wires, which are believed to be of the proper order to prevent lightning flashover, due to tower current, or follow-up of normal frequency current, except possibly in case of unusually severe direct strokes. Very little data on this subject have been accumulated in practise, so that the figures in the table should be regarded as quite tentative:

| Circuit voltage | Insulation to prevent normal frequency follow current (units)* | Maximum tower footing resistance to prevent lightning flashover (ohms)† |
|---|---|---|
| 66 | 8 | 6 |
| 132 | 12 | 8 |
| 220 | 20 | 12 |

*Based on 10-inch disks with 5¾-inch spacing.

†Based on 200,000 amperes in tower.

In the United States and Canada at the present time, there are approximately 2,000 miles of 220-kv line with insulation varying from 12 disks to 18 disks (spaced 5¾ inches, or equivalent). Only one of these lines has been immune from flashover and interruption. However, the interruptions in many cases have been as low as one to three per 100 miles per year.

### IMPORTANCE OF DIRECT AND INDUCED STROKES

The question of relative importance of direct and induced strokes, particularly on the lower voltage lines, is still unsettled. Opinion has drifted toward the direct stroke standpoint. The only direct evidence obtained by measurement is the mass of data secured with the lightning stroke recorder. The larger currents indicated can only be explained on the basis of direct strokes.

However, there have been small currents indicated which might be caused by induced strokes. Strokes to trees and simultaneous voltages recorded on transmission lines also indicate induced surges (see record of stroke on the Ohio Power Company's system, discussed in this paper, and records of several strokes on the Ohio Power and Louisiana Power and Light Companies systems, discussed in the authors' 1931 paper).[1]

### POLARITY OF LIGHTNING STROKES

The additional data which have been obtained on direct stroke currents continue to show that polarity is of dominant importance in the lightning stroke mechanism. Table IV summarizes lightning stroke measurements of transmission line tower leg currents to date, classifying them as to relative current range and polarity and giving the number of line tripouts with each group. These data are from records obtained on the Pennsylvania-New Jersey 220-kv interconnection, Philo-Canton line, and Deepwater-Pleasantville line. In this table only the maximum current of each group of records is included. The accuracy of current values given in this table are somewhat uncertain. The authors feel, however, that no doubt exists as to the polarity classification and that the relative order of current magnitude is sufficiently correct, except where noted, to justify the analysis given.

TABLE IV—LIGHTNING STROKE CURRENT MEASUREMENTS IN TOWER LEGS

| Current range amperes* | | Positive strokes | Correlated tripouts | Negative strokes | Correlated tripouts |
|---|---|---|---|---|---|
| 1,000 | 2,000 | 0 | 0 | 25 | 2 |
| 2,000 | 3,000 | 0 | 0 | 13 | 1 |
| 3,000 | 4,000 | 3 | 1 | 12 | 1 |
| 4,000 | 5,000 | 17 | 0 | 8 | 0 |
| 5,000 | 6,000 | 7 | 0 | 4 | 1 |
| 6,000 | 7,000 | 1 | 1 | 1 | 0 |
| 7,000 | 8,000 | 0 | 0 | 6 | 1 |
| 8,000 | 10,000 | 2 | 1 | 7 | 0 |
| 10,000 | 15,000 | 0 | 0 | 9 | 4 |
| 15,000 | 25,000 | 2 | 1 | 9 | 3 |
| 25,000 | 40,000 | 1 | 1 | 7 | 5 |
| 40,000 | 60,000 | 0 | 0 | 18 | 7 |
| 60,000 | 80,000 | 0 | 0 | 13 | 6 |
| 80,000 | 100,000 | 0 | 0 | 9 | 4 |
| 100,000 | 150,000 | 0 | 0 | 19 | 8 |
| 150,000 | 200,000† | 1 | 0 | 5 | 1 |
| 200,000 | 300,000† | 0 | 0 | 12 | 2 |

*These values are subject to modification on account of uncertain instrument calibration.

†These high current values were obtained with an early recorder arrangement which it is believed gave excessive values.

It is to be noted that the table shows a great number of small negative currents in the range 1,000 to 5,000 amperes, an intermediate group of positive currents, ranging from 3,000 to 6,000 amperes, and a group of high negative currents, ranging from 10,000 to 150,000 and centering about 80,000 amperes.

*Tripouts Occur With the High Negative Currents Almost Exclusively.* This important fact must receive careful attention. Data published by several authors[7,8] indicate that positive cloud-to-ground strokes do take place frequently, probably more frequently than negative cloud-to-ground strokes. However, the data of Table IV show negative strokes to the line to predominate in number and in current magnitude.

The authors of this paper have previously called attention[2] to the influence of electrode shape in relation to polarity in the case of flashover between dissimilar electrodes under atmospheric conditions. The following quotation[9] describes the point very clearly: "Investigation shows that it is the form and intensity of the dielectric field at, or near, the positive terminal which has the greatest effect on the disruptive voltage of the air gap; while the field at, and near, the negative terminal is of secondary importance. Thus, if at constant gap length the positive terminal is gradually changed in steps from a sharp point to a flat plate, while the negative terminal remains unchanged in form, the disruptive voltage changes correspondingly over a wide range. A corresponding change in the physical form of the negative terminal, however, with the positive terminal unchanged in form, varies the disruptive voltage relatively little." In terms of voltage values which are familiar in every day laboratory work, this phenomenon may be stated somewhat as follows:

For dissimilar electrodes, such as point-plane, the breakdown voltage for point positive is one-third or one-fourth that for point negative. As far as laboratory phenomena are concerned, this viewpoint is generally agreed upon. In connection with natural lightning, however, various opinions are held regarding the significance of this electrode shape-polarity effect. It is believed by the authors that the polarity characteristics of available lightning stroke current data strongly indicate the importance of this effect.

The cloud may be considered as a non-conducting electrode of relatively smoothly rounded contours. The earth is a conducting plane from which, in most cases, protrudes rather sharp points, such as trees, steeples, and transmission line towers. Now, it follows very reasonably from laboratory experience, such as described above, that when a conducting projection from the earth is positive in polarity, relative to the cloud, and the cloud potential is sufficiently high, the projection will form a terminal for discharge between the two. Also, the entire current associated with the cloud discharge must pass through this projection, because its presence has initiated the discharge. Furthermore, the negative polarity of the relatively smooth cloud is not at all suitable for the formation of breakdown streamers at the cloud. Accordingly, cloud potential will increase until a suitable projection from the conducting earth provides a high gradient point at the positive terminal. The conditions for minimum breakdown potential under this polarity arrangment are met and the discharge proceeds. This lightning stroke is, it is believed, progressing into a uniform or converging field, a single breakdown channel through which the entire current associated with a negative polarity cloud passes. In laboratory experiments this directive effect of the positive point has been shown to protect an adjacent area of radius of 15 times the projection height.

Where the cloud is positive and the earth negative, projections on the earth's surface have little directive effect.[2] Here it appears that breakdown streamers from the positively charged cloud,[10] originating at the cloud, proceed with considerable branching toward the seat of the induced charge. The positive polarity of the cloud is suitable for streamer formation, and the usually diverging cloud field gives rise to branching. Under these conditions, laboratory tests have shown a protected area adjacent to a projection of radius equal to two or three times the projection height. A standpoint, such as that described above, is well in accord with the data of Table IV. The high negative cloud discharge currents, severe in that they practically alone cause line tripouts, reach the line structure frequently because of its directive effect as a positive polarity projection above the conducting plane of the earth. Positive cloud-to-ground strokes reach the line less frequently, as again shown by the table, and then are within the intermediate current range 3,000 to 6,000 amperes and do not often cause tripouts. It is agreed, of course, that with sufficiently high tower footing resistances, currents of this range would produce flashover. The positive strokes to ground do not reach the line in greater numbers in spite of their frequency, because of the lack of directive effect of the line charged negatively. Also, such strokes when they do chance to strike the line are less severe because of extensive streamer branching, which exhausts the cloud energy and gives lower tower currents. The large group of low current records are believed not to be due to direct strokes, but of induced origin. These records are principally of negative polarity, as should be the case if induced by nearby positive cloud-to-ground strokes. Such nearby positive strokes are in accord with the above analysis.

To maintain the correct standpoint regarding the mechanism of cloud discharge, it must always be kept in mind that the cloud potentials are building up relatively slowly. The lightning flash awaits a breakdown gradient at some point in the cloud field. Thus, the field configuration, depending upon cloud and ground conditions and polarity, are critical. When these are lost sight of in consideration of uniform fields and plane electrodes, the true elements of the picture are lost. For instance, it is generally agreed that in certain localities lightning storms are frequent, but transmission line service interruptions are rare. When this is considered in the light of the polarity effects described above, possible explanations are readily forthcoming. The relative positions of the positive and negative cloud charges and their distances to ground are important. Difference of opinion exists regarding the normal distribution of charge, whether the two polarities are on the same level or one is above the other is somewhat uncertain. One series of data[7] indicates strongly that the positive charge is below and the negative above. Another very thorough study[8] of the mechanism of accumulation of cloud charges reverses this relative position. Probably the atmospheric conditions changing greatly with geographical location and season make for considerable variation in charge position. At this time, it is sufficient to note that an elevation of the negative charge position of the cloud relative to ground without change in positive charge location would probably eliminate many of the severe negative strokes without affecting greatly the number of positive cloud-to-ground strokes, or causing a noticeable reduction in lightning severity from the casual observer's point of view. Of course, an elevation of the entire cloud would decrease the cloud-to-ground and increase the cloud-to-cloud strokes.

## LABORATORY LIGHTNING TESTS

Many instances, wherein attempts have been made in the laboratory to demonstrate the mechanism of natural lightning have led to uncertain conclusions. Some observers doubt the value of such tests entirely, while others see in almost every laboratory discharge some aspect of natural lightning. Somewhere between these two must lie the most valuable standpoint. Many laboratory observers have made helpful contributions and further experimentation is very desirable. Several factors, however, should be kept in mind when laboratory studies of the mechanism of natural lightning are being conducted, so that uncertainties will be eliminated. Field conditions should be simulated as closely as possible. For instance, a study of conditions surrounding the precipitation of the stroke should utilize as close a representation as possible of natural conditions. It is not difficult to show that branching streamers may be directed away from a negative electrode if suitable electrode arrangements are utilized, but such a test does not justify the viewpoint that branching away from a negatively charged cloud occurs in thunderstorms.[11] Also, since impulse testing of insulators has become common, observers have endeavored to interpret some of the results obtained in this field as indicative of aspects of the mechanism of natural lightning. It is not believed that this will prove to be a helpful practise. The slowly increasing voltage of the cloud is not simulated by the rapid surge of the impulse. Particularly, time lag effects enter into the impulse testing results in entirely different ways than are obtained in direct-current testing. Careful laboratory experiments[12] have shown that the point-plane effect, which has now been shown to dominate the natural lightning picture, grows less pronounced as the time duration of the impulse decreases. Again, in impulse testing overvoltages are always applied and in natural lightning only the lowest flashover voltage is obtained with continuous potential. Of course, the field for such investigations is wide and only careful attention to such details will produce good results.

### CONCLUSIONS

The overhead ground wire is definitely shown to be effective in reducing line tripouts.

The beneficial effects of low tower footing resistance are apparent from the data and analysis.

The counterpoise is shown to be effective in securing low tower footing resistance.

Line insulation and permissible tower footing resistance specifications, which will render the lines practically immune from flashover, may be written.

For a good understanding of how direct strokes which cause tripout chance to terminate on the transmission line and reach current values sufficient to give insulator flashover, it is necessary to consider polarity characteristics of the cloud and of flashover between dissimilar electrodes.

## Discussion

**A. E. Davison:** Engineers usually are so busy protecting those transmission lines and works which are very much exposed to weather hazards, more particularly lightning, that they neglect to call in the physicist. Some engineers even go so far as to advocate lightning proof designs and terminal equipment. Are these attempts to secure lightning proof lines always the most economical methods by which the continuity of services can be attained?

There is considerable evidence according to Dauzere, who addresses the International High Tension Conference and other French technical and physical organizations, that the incidence of lightning is not as uniformly spread over large areas as a layman would expect for such an extremely fortuitous natural phenomenon as lightning. He pictures electrical pockets in the lower atmosphere through which lightning discharges may be expected to be more frequent. As compared with his suggestions, one would naturally expect that variations in elevation of terrain should affect the discharging of storm clouds moving across an area and that the sides of escarpments and mountains would be marked extensively by lightning discharges and would be frequently burned over. This assumption is not always borne out by observations.

Turning to the protection of rural buildings against lightning, some of us can recall a considerable relief upon having rodded a transmission line or a set of buildings, electrically. The lightning does not seem to strike as often. Is this some pyschological conclusion or is it a fact? Do these lightning rods drain off the effectiveness of a discharge between earth and clouds to the extent that there frequently is no sudden dynamic or electrical display as storm clouds pass? Many engineers know of quite local areas where strokes are relatively frequent. Transmission men, especially, know of lines or sections of lines which they would, after the fact, like to re-route on account of lightning outages. The objectionable locations may, for instance, be on the sides of hills or mountains and in other cases in comparatively flat areas. Why?

This discussion is submitted in order to suggest that utility engineers might very well ask a physicist, or men who are qualified to study geophysical conditions to look into the terrain more fully. It may be that engineers will thereby be directed when projecting their longer lines to go around an area. This would alter the apparent economies by 2 to 5 per cent due to an increased length of line, but would avoid districts recognized by geophysical examinations and analyses to be subject to lightning. They might be directed to place a line on areas recognized to be comparatively free from lightning effects.

If lightning is responsible for by far the largest group of interruptions to services, then it is desirable that we should study the phenomenon more fundamentally rather than give attention exclusively to the practise of trying to design relatively expensive transmission lines and connected apparatus sometimes referred to as lightning proof.

**I. W. Gross:** Theory and practise must go along together, if a firm foundation is to be laid for our knowledge of lightning, and the application of effective protective measures to lines and apparatus. Considering the factors still unknown in the mechanism of a lightning stroke itself, and its effect on a transmission line, it is clear that theory alone may lead to erroneous and impracticable conclusions if not checked by actual experience. On the other hand, actual operating experience alone may lead one astray, if results are not carefully analyzed and coordinated with theory. Certainly, slower progress will be made if we do not check over experience with theory continually.

That direct strokes to a transmission line can take place, in many cases without line tripout, is a statement which would hardly be made some six years ago. However, the data in this paper prove this actually does take place.

The beneficial effect of lowering the tower footing resistances to prevent line flashover has been predicted by theory, stated by general considerations, and definitely proved by experience, as given by the summarized data in this paper and that of Mr. Sporn, see page 482 of this issue.

The statement is made by the authors that "Tower footing resistances up to 75 or 100 ohms are tolerable". Does this apply only to direct strokes? Certainly, this is not true if the line outages due to lightning, irrespective of the origin of the lightning, are to be reduced to a reasonable number. In Mr. Sporn's paper it is shown that, on the average for ten different lines, increasing the average tower footing resistance from 5 ohms to 20 ohms increased the line outages 100 per cent. At the particular towers where flashover occurred on 5 lines, about 75 per cent of the flashovers occurred at towers having a footing resistance less than 75 ohms, and over 20 per cent of the flashovers at towers having a footing resistance less than 5 ohms. Tower footing resistances considerably lower than have been talked of in the past, appear to be necessary to make a line immune to lightning flashover.

At the top of page 478 is given a table of the number of insulators, required for different voltage lines, which are referred to as being of the proper order to prevent follow-up of normal frequency current. The experience on the lines of the American Gas and Electric Company indicates that the insulation suggested is too low. In fact we have almost come to the conclusion, based on recent experience, that it is practically impossible to overinsulate a line, within practical limits, so that it will be immune to 60-cycle follow-up current.

Table I shows a two-year record of four lines operated in the 33- to 66-kv voltage range. In the case of the Muncie-Anderson 33-kv line, with 132-kv insulation (10-5-1/8 in. units) the outages on a 100-mile per year basis were 10.8 against a system average on some 1,500 miles of 132-kv line, of 16.7 outages. This overinsulation certainly does not look promising, as a means of preventing 60-cycle follow-up current on low voltage lines, even with tower footing resistances as low as 5 ohms, which was the case with the Muncie-Anderson 33-kv line.

**W. W. Lewis and C. M. Foust:** The statement referred to by Mr. Gross, namely, that "Tower footing resistances up to 75 or 100 ohms are tolerable," refers only to induced strokes. Under the heading "Direct Strokes" tower footing resistances not over 6 to 12 ohms are recommended.

TABLE I—LIGHTNING OUTAGES ON OVER INSULATED LINES—1930-1931

American Gas and Electric Company Steel Tower Lines

| Line | Circuits | Ground wires | Tower footing resistance | Operating kv | Insulators and spacing | Outages/100 miles of line per year |
|---|---|---|---|---|---|---|
| 1. Deepwater-Pleasantville | 2 | 2 | 45.5 | 66 | 10–4–3/4 | 12.3 |
| 2. Beaver Creek-Hazard | 1 | 1 | | 44 | 10–5–1/8 | 19.4 |
| 3. Muncie-Anderson | 2 | 1 | 5.0 | 33 | 10–5–1/8 | 10.8 |
| 4. South Point-Portsmouth | 2 | 1 | | 33 | 10–5–1/8 | 24.0* |
| 5. 132-kv system 2-year average (1930-31) | | | | | | 16.7 |
| 6. 66-kv line—less outages due to flashover at graded insulators | | | | | | 7.9 |
| 7. 44- and 33-kv lines—less outages due to flashover at graded insulators | | | | | | 13.6 |

# Lightning Experience on 132-Kv Transmission Lines of the American Gas and Electric Company System

## 1930-1931

BY PHILIP SPORN*

Fellow, A.I.E.E.

*Synopsis—This paper, which is a continuation of a four-year operating record of an extensive 132-kv transmission system under lightning conditions, presents and discusses the record for 1930 and 1931.*

*Operating experience is given on:*

*1. Yearly line outages due to lightning for all lines.*

*2. Severity and frequency of lightning storms over the system for a three-year period.*

*3. Frequency of double circuit outages.*

*4. Extent of line and station apparatus damage.*

*5. Effect of tower footing resistance in reducing lightning outages.*

*6. Reduction in tower footing resistances by the use of driven ground rods and counterpoises.*

*7. Effect on lightning outages by overinsulation.*

*8. Relative frequency of single-phase, two-phase and three-phase line faults.*

*9. Location of lightning flashovers on the line in reference to top, middle and bottom conductors.*

*Conclusions are drawn from the results of the operating experience on these lines.*

### INTRODUCTION

In the final analysis, field experience, properly analyzed and interpreted, is the only safe criterion for judging performance of any engineering structure, piece of equipment, or system embodying them. This holds true particularly for transmission lines where a great deal of time must of necessity elapse before it can definitely be determined whether or not satisfactory results have been obtained from new designs, design changes, or remedial measures adopted. It is the purpose of this paper to give such an analysis of a large 132-kv transmission system, where an attempt at keeping accurate and careful records of lightning performance has been made, and, in so far as possible, interpret these records and their bearing on the various phases of the lightning protection problem.

### DESCRIPTION OF SYSTEM INVESTIGATED

The system investigated comprises, at the present time, some 1,450 miles of right-of-way, including approximately 850 miles of double-circuit line, 600 miles of single-circuit line, and a total of 2,200 miles of three-phase circuit. The general extent of the system and territory covered has been previously described.[1]

Since 1929 when the last record of lightning performance on the system was reported before the Institute, the interconnected system has been increased by approximately 250 miles of right-of-way (400 miles of three-phase circuit).

Most of the transmission lines are of two-circuit steel tower[1] construction, the conductors being in vertical arrangement on each side of the tower, and in most cases at least one protective ground wire is employed. The only two wood pole lines (Logan-Sprigg and Sprigg-Beaver Creek) do not have ground wire protection. Three lines have two ground wire protection; the Twin Branch-Benton Harbor Line and the Deepwater-Pleasantville Line have one ground wire located at the peak of the tower and one directly underneath at the approximate level of the second crossarm. The Windsor-Canton Line has two ground wires, one above each circuit.

All lines are constructed with 132-kv insulation and are operated at 132 kv with four exceptions. These are the Beaver Creek-Hazard Line which is operated at 44 kv, the Deepwater-Pleasantville Line which is operated at 66 kv, and the South Point-Portsmouth and Muncie-Anderson Lines which are operated at 33 kv. It is planned eventually to cut all these lines over to 132-kv operation. Some of the details of design and construction of these different lines are listed in Table I.

The spacing of conductors on steel tower lines is in the order of 21¾ ft or more between circuits and 13 ft vertically between phase wires. The ground wire (where only one is used) is located at the tower peak approximately 10 ft above the level of the top conductors. On tower lines provided with only one ground wire, the lightning flashover between the ground wire and nearest line conductor, is in the order of 5,000 kv at suspension towers and 5,800 kv at dead-end towers. In midspan these flashover voltages are 20 to 35 per cent greater due to the difference in sag of the line and ground wires. The impulse flashover at the insulator strings (assuming an average length of string of 50 inches) is in the order of 1,250 kv. All these flashovers are on the basis of crest flashover with a ¼ by 5 microsecond impulse wave.

The type of country through which these lines extend varies from flat country where the tower footing resistances are in the order of 2½ ohms, such as in Indiana, to very hilly mountainous country where footing resistances reach magnitudes of 200 ohms and over.

### PROTECTIVE EQUIPMENT

The general type of lightning protective equipment supplied on the 132-kv system consists of lightning arresters at all major substations, graded insulation at station entrances, the use of ground wires on most lines (see above), and in a few cases the installation of ground rods and/or counterpoises at the base of the line towers. Additional ground rods were installed on the Twin Branch-Benton Harbor Line before it was placed in service and on the Deepwater-Pleasantville Line after it had been placed in service. Counterpoises, that is, buried conductors, have been installed on parts of the Deepwater-Pleasantville and Glenlyn-Roanoke Lines since they have been placed in service. The counterpoises were installed on the Deepwater-Pleasantville Line in the summer of 1931 and on the Glenlyn-Roanoke Line in the summer of 1932.

Total storms reported by operators at above stations

Graded insulation at station entrances consists of reducing insulation on from one tower to a half mile back from the station, by one or more insulator units below the standard suspension string. This, in general, leaves the lightning flashover at the station limited to the flashover of from eight to nine standard insulator units provided with grading shields.

### OPERATING PERFORMANCE

*Line Outages.* The detailed operating performance of the 31 lines is given in Table I. The number of outages in 1928 to 1931 inclusive is summarized in Table II. It will be noted that the number of outages on a unit basis is considerably greater in 1929 and 1931 than in 1928 and 1930. The reason for this may be attributed to the more severe lightning seasons in 1929 and 1931 than in the other two years. Data bearing out this statement are shown graphically in Fig. 1.

This record has been compiled from the reports of operators located at the various substations over the system; it shows not only a greater number of storms in 1929 and 1931 but also an increased severity during those two years. The contrast between 1929 and 1930 in each of the three classes of storms (very severe, severe, and light) for which data are given is particularly striking, and again shows the necessity for some accurate measure of lightning severity if proper comparisons are to be made of line performance from year to year.

Of the three years for which lightning storm records are available, 1929 apparently shows up as the worst; and the outage record given in Table II is worse in 1929 than in any other of the four years shown.

TABLE II—AVERAGE LINE OUTAGES PER 100 MILES OF LINE PER YEAR

| | 1928 | 1929 | 1930 | 1931 |
|---|---|---|---|---|
| All lines | 13.5 | 21.6 | 13.7 | 19.8 |
| Two-circuit lines | 17.7 | 23.3 | 12.5 | 15.9 |
| One-circuit lines | 10.0 | 17.8 | 15.2 | 25.1 |
| Lines insulated for 132 kv but operating at 66 kv | | | 14.1 | 10.5 |
| Lines insulated for 132 kv but operating at 66 kv, less outages at graded sections | | | 10.5 | 5.3 |
| Lines insulated for 132 kv but operating at 33 and 44 kv | | | 13.4 | 19.2 |
| Lines insulated for 132 kv but operating at 33 and 44 kv, less outages at graded sections | | | 13.4 | 11.8 |

Another point of interest brought out in Table II is the record of lines insulated for 132-kv but operated at a lower voltage. These lines on 33-, 44- and 66-kv operation show, it is true, a smaller number of outages than lines similarly insulated but operated at 132-kv. This is particularly so if the records are compared on the basis of omitting those outages which have been charged to flashovers on the graded insulation sections of the line. But even under those conditions, the reduction is not at all in line with what one might expect from the large reduction in operating voltage. It would appear, therefore, that it is not a practicable matter to so over-insulate a line that it will be immune to the follow-up current in the case of lightning flashover, even when the operating voltage is as low as 33-kv and the ratio of insulation employed is 4:1 of that normally used.

### DOUBLE-CIRCUIT LINE OUTAGES

In previous records[1] it has been shown that, on two circuit lines, in only 15 to 29 per cent of the cases of outage did both lines trip. In 1931, however, the percentage of outages where both lines tripped out during lightning disturbances rose to 40 per cent. This record is shown graphically in Fig. 2. While the outages per 100 miles of line per year have, in general,

decreased from 1926 to 1931 (excluding 1929 which was a bad lightning year) it is observed that the percentage of outages involving both lines has increased. On the other hand, it will also be noted that the total miles of two circuit lines on the system has also increased. It might be deduced from this fact that the increase in the size of the system, that is, the connected kva capacity had also increased. This, in fact, has been the case. A 165,000-kva generator was installed in the spring of 1929 at the Philo Plant which is roughly at the center of the transmission system; and in August 1929 an interconnection with another large system was placed in continuous service at the extreme western end of the system. It is believed that this increased system capacity has sufficiently maintained voltage in some cases so that line lightning flashovers which previously had in some cases not developed into short circuits on the line, did after 1929 become a factor in actually tripping out the second circuit.

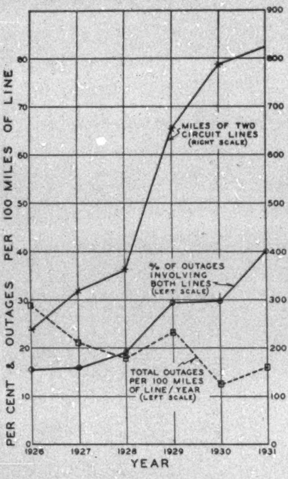

Fig. 2—Lightning Performance of Two-Circuit Lines

## Line Damage

The record of damage to line wires, insulators, and arcing protection is given in Table I for each line. The fact that the "cases of damage per line outage" runs in the order of 0.2 to 2.0, where the records are complete, with an average of approximately 1.1 shows that the majority of line tripouts are accompanied by one but not more than two flashovers. This indicates as would be expected that line flashover is confined close to the point of origin of the electrical disturbance. The fact that comparatively few insulators, burned conductors, or hardware have been observed, and rarely of sufficient importance to require servicing, shows that the arcing protection has been very effective in preventing severe damage to the line. The protection afforded by the rings to line insulators is in line with prediction and past experience.

During the three years' operation 1929-30-31, no trouble from lightning on the 132-kv lines has made necessary holding the line out of service longer than the time necessary to reclose the switch.

## Station Apparatus Damaged

The three-year (1929-30-31) records of damaged apparatus at substations over the entire interconnected 132-kv system shows that lightning damaged one transformer, nine coupling condensers which were used for the communication system, and one insulator on the lightning arrester gap at one substation. At the substation where the transformer was damaged, it is important to note that lightning arrester protection had been provided. The failure of this large number of coupling condensers has been very definitely fixed as due to a defect in the inherent design of the apparatus, as at the time these condensers were installed no attempt had been made, due to the complete lack of reliable impulse data, to coordinate their insulation strength with that of the other station apparatus on a lightning basis.

It should be noted that the use of lightning arrester protective equipment at each of the substations did not render all the station apparatus immune to lightning failure. It is quite true, however, that the record of only one transformer failure from lightning in three years in this large number of stations shows that the stations are operating with a high degree of protection against lightning although this protection is not 100 per cent perfect.

### The Effect of Tower Footing Resistance

In a paper describing the 1929 lightning experience,[1] the effect of tower footing resistance of lines equipped with ground wires was fully discussed, and it was pointed out that if a ground wire is to offer a high degree of protection against lightning flashover at the tower, the tower footing resistance must be relatively low—in the order of 5 ohms or less. Some further light is thrown on this phase of the problem by the analysis made for the last three years, from this point of view.

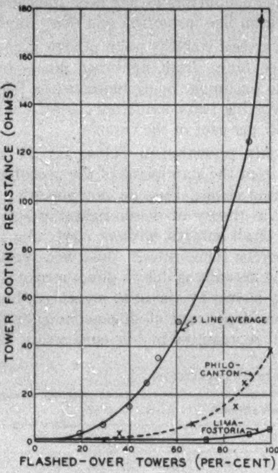

Fig. 4—Tower Footing Resistance Where Flashover Occurred 1929-30-31

The relation between the average tower footing resistance of ten different lines and the number of outages per one hundred miles of line per year for three years is shown in Fig. 3, each plotted point representing the specific performance of a particular line plotted against the average tower footing resistance of that line. The average performance for the three years' operation is shown by the dotted curve. This, as well as the three individual curves, shows a distinct reduction in outages as the tower footing resistance is lowered. The reduction of tower footing resistance from 80 ohms to 40 ohms results in a decrease in outages of 13 per cent; on the other hand, a 50 per cent reduction in tower footing resistance from 10 ohms to 5 ohms reduces the outages 35 per cent. Since Fig. 3 gives data for ten different lines over a three-year period, the benefits indicated from the lower tower footing resistance cannot be laid to mere chance.

To trace thoroughly the effect of tower footing resistances, the resistance values at towers where flashovers have actually been observed have been studied for five lines and are shown graphically in Fig. 4. These curves give the highest value of tower footing resistance encountered in any percentage group of flashed towers both for two separate lines and for all the five lines indicated. It will be noted, first, that tower footing resistances, even as low as 5 ohms, do not make a line immune to flashover from lightning. Second, on the five lines for which data have been summarized in Fig. 4, 50 per cent of the flashovers occurred at towers having a footing resistance less than 30 ohms, and 30 per cent of the flashovers occurred at towers with a footing resistance less than 10 ohms. Over 20 per cent of the flashovers occurred at towers with footing resistances less than 5 ohms.

Analyzing the effect of tower footing resistance still further, Fig. 5 shows that where the tower footing resistance is low there is less disturbance to the line from lightning storms. For example, with the tower footing resistance of 2½ ohms there has occurred only one line outage for every 10 storms. Where the average tower footing resistance of the line has been 40 ohms there has been one outage for every lightning storm observed. As the tower footing resistance becomes higher the outages per storm, or the storms through which the line can ride without an outage, become less than one, that is, on an average over a period of time, more than one outage occurs per lightning storm.

## LOCATION OF LINE TROUBLE

In an attempt to determine how lightning has initially come on the line an analysis has been made of the location of trouble on the line conductors by three methods: first, by means of physical inspection of the line (tower climbing inspection), second, by relay target indications, and third, in one special case, by an automatic oscillograph. In Table III is given the record of line flashovers on top, middle, and bottom conductor as observed from the line inspection on five different lines. The same type of data is given in Table IV from the record obtained from the relay targets; and in Table V are given similar data obtained from automatic oscillograph records. These tables show a preponderance of single-phase trouble, 86.4 per cent being recorded by the line inspection, 64.3 per cent by the relay target indications, and 60.6 per cent by the oscillograph. Thus it appears that the majority of lightning troubles result in single-phase fault currents but roughly divided about equally on top, middle, and bottom conductors. This of course does not necessarily mean that these troubles start as single-phase lightning faults, as it has been proven in the past that system power current will not, under certain conditions, follow. For example, if a conductor on which lightning flashover takes place is at or near zero voltage of the normal 60-cycle wave power current does not follow. Undoubtedly the data in Table V are far more accurate than in Tables III and IV as Table V is based on data obtained from an oscillograph located at Glenlyn whereby the phase voltages of the system were recorded. It should be noted, however, that the faults are located in the same general position with respect to top, middle and bottom conductors as has been indicated by data obtained from line inspection and relay targets.

From a system stability point of view it appears that three-phase faults from lightning causes occur very rarely, the maximum being indicated as 8.8 per cent. Faults involving two conductors comprise a maximum of about 27 per cent of the trouble.

If the data presented in Tables III, IV and V are analyzed from the standpoint of the probable origin of the lightning stroke, they do not present a clear cut case for the theory of direct lightning strokes being the cause of all outages, without stretching the theory to a dangerous tenuousness. Just what percentage of the outages actually is due to direct stroke is of course not clearly shown by the data presented, but the fact that of the 74 per cent of single-conductor flashovers, 23 per cent represented middle conductors, 22 per cent

bottom conductors and only 29 per cent top conductors, makes it very difficult to explain how direct lightning strokes are responsible for all outages on the lines of this particular system.

### COUNTERPOISES AND GROUND RODS

To show the effect of ground rods driven at the base of a tower in reducing the tower footing resistance, Table VI has been compiled. At each tower five 1 inch by 20 feet galvanized rods were driven and each rod treated with 100 lb of rock salt. The reduction in tower footing resistance by the installation of these rods is approximately 50 per cent, the ratio of resistance before and after installation of the rods being, for the 20 towers, 52 per cent.

[2]From Table V (1930-1931).
[3]From Table III (1929-30-31).
[4]From Table IV (1929-30-31).

The reduction in tower footing resistance by the use of counterpoises is shown in Table VII. The counterpoise in this case consisted of 4 galvanized iron strips approximately 1/16 in. by 2 in. in cross section, two lengths each extending 150 ft away from the tower in opposite directions and parallel to the line, and two lengths extending similarly at right angles to the line, each being approximately 40 feet long. The total length of strips connected to each tower is therefore 380 feet. This metallic strip was buried approximately 18 inches in the ground where soil conditions permitted. The reduction in tower footing resistance is shown from Table VII to be exactly 50 per cent.

Since these ground rods and counterpoises have been in service only a comparatively short time, the beneficial effects which are expected from their use have not as yet been proved. The limited data available, however, seem to indicate that the counterpoise in particular is giving a degree of protection against lightning considerably in excess of what is indicated by the mere numerical reduction in tower footing resistance.

### CONCLUSIONS

1. Reasonably good protection against lightning has been afforded station apparatus on this system by the use of lightning arresters and grading insulation at the substation as is evidenced by the failure of only one power transformer during the three years covered by this investigation. The fact that a transformer failed although protected by a lightning arrester still shows that there is something to be accomplished before we can provide 100 per cent protection to station apparatus.

2. Grading shield protection on the line itself has proved very effective as evidenced by the relatively small number of damaged insulators and burned conductors—troubles which in no case have required a line to be kept out of service for repair. Line inspections have shown that the grading shields have taken the power arc in the majority of cases.

3. Transmission line outages are materially reduced by reduction of tower footing resistance. However, tower footing resistances as low as 3 ohms do not guarantee immunity from lightning outages even though the lines are equipped with an overhead ground wire.

4. In case of two circuit lines the per cent of outages affecting both lines increases as the size of the system (kva generating capacity) is increased.

5. No evidence of direct hits to the line wires themselves between towers has been found. (Previous to the installation of a ground wire on the Lima-Twin Branch Line evidence of burned conductors in the span was reported.)

6. Increasing line insulation considerably on lines of low operating voltage (132-kv insulation for 33-, 44-, and 66-kv lines) has not been sufficient to prevent follow-up current and consequent line outage in case of lightning flashover.

7. Lightning flashovers on a typical group of lines causing power follow-up resulted in single-phase faults in approximately 73.8 per cent of the cases (divided as follows: top 28.9 per cent, middle 22.8 per cent, bottom 22.1 per cent) two-phase faults in 19.6 per cent of the cases, and three-phase faults in 6.6 per cent of the cases. With this record, it is hard to justify the theory that all or even the majority of lightning outages on these lines have been the result of direct lightning strokes to the lines, overhead ground wires, or towers.

8. The only line using two overhead ground wires directly above the transmission circuits has throughout a period of years shown an excellent performance even though the average tower footing resistance of the line was 12 ohms. On two other lines using two ground wires, one directly below the other, the outage per one hundred miles of line per year is less than the average although still not as good as that line where both ground wires are above the transmission circuits.

9. The large number of lightning outages per one hundred miles of line per year on wood pole lines operated at 132-kv seems to indicate that the degree of lightning protection assumed to be possible with the use of wood or lightning insulation has not been obtained in this case. It may be, however, that since in both cases these wood pole lines are not equipped with the overhead ground wire, that this may account in part for the excessive number of line outages in these cases.

### ACKNOWLEDGMENT

The author wishes to acknowledge the help and encouragement received from the organizations of each of the operating companies whose transmission systems are described in this paper and who have cooperated in the gathering of the data and in the investigations described. He also wishes to acknowledge the valuable work of Mr. I. W. Gross in the gathering, correlating and development of the data and the help in the preparation of this paper.

## Discussion

**Everett S. Lee:** There is a great difference between the situation today and that in 1925, which may be taken as the year when the last romance with lightning by the electrical engineers began. That was the year of many storms; the wreck of the Shenandoah came about that time.

Mr. Sporn in a paper in the TRANSACTIONS for 1926[1] says: "While these troubles were occurring, it was impossible to get any accurate data as to what was happening. Lines were flashing over, insulators were being shattered, the conductor was being burned, the field forces were too busy trying to place the line in an operating condition with minimum delay to be able to give very much attention to the details of what was happening. Things were happening so thick and fast that there was no opportunity to stop and consider the matter calmly. With the approach of the end of the lightning season a little more time could be taken to determine what had actually happened to make an intelligent analysis." Most of us at one time or another have found ourselves in the midst of kindred troubles so that this graphic description finds a human response within us.

Coincidently with the need for analysis, which was evident generally, came the necessary tools, for Messrs. Cox and Legg presented a paper[2] at Saratoga in 1925 telling of the klydonograph and the use of Lichtenberg figures as a means for measuring surge voltages. At the same convention, Messrs. McEachron and Wade gave a paper[3] describing the application of the cathode-ray oscillograph to time-lag studies of sphere spark gaps, technique in the same field.

Then started the romance of the engineer with lightning. Out into the field they went on many different systems—east, west, north and south, equipped with devices advancing year by year. Klydonographs and surge-voltage recorders were dotted thickly along transmission lines to measure the voltages there. Up went the recorded voltages, 1 million, 2 million, 3 million, 5 million. The cathode ray oscillograph, laboratory instrument of the scientists was taken out into its mountain home to await the coming of the lightning which the observers prayed would come in abundance and which the operators prayed would stay away with its devastation. But it did come and the cathode ray oscillograph, waiting, revealed the wave form of the voltages measured by the surge-voltage recorders. This brought microseconds into the picture and the engineers talked glibly of 1 microsecond and 10 microseconds, and yesterday and today we are talking standardization of these values as we would talk standardization of volts and ohms and amperes and degrees.

---

[3] *Study of Time Lag of the Needle Gap*, A.I.E.E. TRANS., Vol. XLIV, 1925, p. 832.

And so the romance continued. With the measurements of lightning voltages came the need for rating the severity of lightning, so the storms were counted, and the lightning severity meter was devised and used. Then came the wish to know more about the currents involved, and the lightning stroke recorder was developed and more data appeared along the transmission lines, and we began to talk of 50,000 and 1,000,000 amperes. And in the paper by Messrs. Lewis and Foust, we find an intensive study of the tower currents from lightning stroke recorded records and a new instrument referred to, the surge-crest ammeter, described elsewhere in the technical press, used for an extension of this work.

With the gathering of all these data and the intensive analysis accompanying it, the transmission engineers began to talk of new schemes, the counterpoise came into the picture to supplement the ground wire; lightning protection wires appeared, and through it all, the ground wire of old rode safely through the storm, being rendered even more effective by these devices. New words came into prominence, rationalization and coordination, and now these are subjects for standardization. Direct strokes and induced strokes became the subject of conversations, papers and discussions, and today the knowledge of these is more certain, though apparently not yet the subject for standardization.

Through all of this romance, there has been brought to the A.I.E.E. the results of those who have worked so wonderfully and so effectively in this field. Their reward is their satisfaction of a work well done. And unlike that of Mr. Sporn's experiences related in his 1926 paper, we find in this present paper these words:

"The fact that comparatively few insulators, burned conductors, or hardware have been observed, and rarely of sufficient importance to require servicing, shows that the arcing protection has been very effective in preventing severe damage to the line. The protection afforded by the rings to line insulators is in line with prediction and past experience.

"During the three years' operation, 1929-30-31, no trouble from lightning on the 132-kv lines has made necessary holding the line out of service longer than the time necessary to reclose the switch."

These are some of the results of the work which came after the intelligent analysis. All problems have not yet been solved, but we believe they are on a substantial basis.

In looking over some of the reports forming a basis of these papers, the writer found the following tabulation:

| Year | |
|---|---|
| 1927 | 100 |
| 1928 | 100 |
| 1929 | 130 |
| 1930 | 100 |
| 1931 | 70 |
| 1932 | 50 |

These are storm severity records for one of the large transmission systems of the east based on storm reports and line operation. Similar figures given by Mr. Sporn for his system do not show the same relative severity decrease in the last two years, even though his line performance record shows more satisfactory attainment. These data are a necessary part to the whole picture in order that proper credit may be given to the design of the line and associated apparatus throughout in view of the line performance. There is still much room for advance in the design of instruments for recording lightning severity, and though the problem is difficult, and the expense great, it is to be hoped that success will ultimately be achieved in this regard.

**A. O. Austin:** The very complete information upon the operating records of the American Gas and Electric Company's system is worth many times the expense and time required to collect and compile, as records of this kind eventually make it possible to compare different types of construction and methods of operation. What we really need is a comparative reliability or performance index for different types of construction, so that new lines can be designed and installed upon a better engineering basis. There are so many factors involved that it would seem almost impossible to devise a scheme of analysis which would provide an operating index. However, continued work upon a scheme shows that much can be accomplished when checked with operating results such as those given by Mr. Sporn, and it is hoped that the Institute will have the benefits of further reports of this kind.

The effect of high towers in increasing the number of hits to the system as well as the length of span in increasing the impedance which affects the drainage of the charge for a direct hit all show their effect upon operation, other conditions being equal. It would seem that high ground capacitance rather than a low ground resistance is an essential. The presence of water in the ground lowers the ground resistance but greatly increases the capacitance. This is of material benefit not only in absorbing the charge but in lowering the effective height or exposure of the line. High ground capacitance may be obtained even for conditions where a low ground resistance is not possible by the use of a counterpoise or a grid system radiating from the tower.

It has long been evident that a line may have an entirely different exposure for negative and positive strokes. While in general negative strokes are much fewer their tendency to cause tripouts is much greater as the current values probably are very much higher in most cases, so that the impedance drop may be a factor which probably should be given more attention. Shortening the span not only reduces the impedance in the ground wire but makes it possible to lower the effective height of the system. A relatively low transmission line without ground wire protection possibly may have fewer tripouts, even though every direct hit to the system causes a tripout, than a system having a greater exposure but in which a portion of the hits only causes tripouts.

Reducing the impedance of ground wire systems by shortening spans, cross connecting the ground wires, and by providing grids or counterpoises certainly will be given much more attention in the future than in the past. This together with the decreased exposure will tend to provide much higher reliability.

Mr. Sporn has pointed out that the possibility of trouble due to induced voltage cannot be overlooked. Fortunately the gradient affecting the transmission line is not very high for most lightning discharges even in the vicinity of a direct hit. However, where the gradient is high the release of a bound charge easily can cause flashover, as shown by Mr. Sporn's report. Very high ground wires are costly and increase the exposure, and when they are connected to the towers it must be remembered that the flashover voltage of the insulator must be depended upon to prevent a tripout unless the impedance of the path of the discharge to ground is very low. The path taken by a discharge following a direct hit indicates that the wave fronts are exceedingly steep.

On large interconnecting systems it frequently is difficult to limit the normal frequency current from phase to ground, but where this can be accomplished a flashover may not necessarily result in a tripout, as the negative coefficient of the arc is an important factor in maintaining a path of low resistance to ground. Any reduction in the normal frequency current tends to allow quenching of the arc due to radiation. Increasing the effective flashover voltage and limiting the normal frequency current by resistance or reactance in the neutral will do much to quench the normal frequency arcs tending to follow a flashover from lightning, and undoubtedly can be used to improve the operation for many systems.

It is to be hoped that more operating records will be available, so that the effect of various factors upon the relative performance can be used to obtain an operating index which will be a guide to designing as well as the treatment of existing lines.

**V. M. Marquis:** In the past it has been necessary to rely to a great extent upon tower climbing inspections and relay targets to determine the phase or phases involved in any flashover due to lightning. Relay targets are not always positive in their action: and tower climbing inspections have the disadvantages that (at least in some districts where inspections are rather infrequent) it is difficult definitely to correlate visual damage with specific outages.

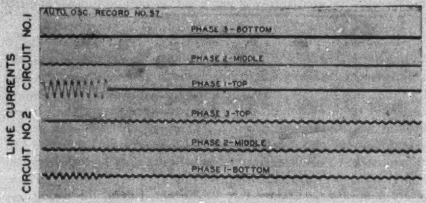

Fig. 1—Single-Circuit Outage Due to Lightning

No. 1 circuit—10 cycles to clear
Glen Lyn-Roanoke 132-kv double-circuit line, August 29, 1932—11.06 a. m.

An additional means of checking the phase location of damage on transmission lines has been made possible with the development of the latest type of automatic magnetic oscillograph. This has overcome the limitations of the older types with respect to the slow starting characteristics and the necessity of changing films after each or at best after a limited number of records. Also, with the new type of oscillograph, all but about the first half cycle of the follow-up current is recorded, and such a record gives a most definite and positive means for determining the phases in trouble and the sequence of events after the appearance of the dynamic follow-up current. Such an instrument should prove very beneficial in the study of lightning from the standpoint of the follow-up normal frequency currents that result from a lightning flashover.

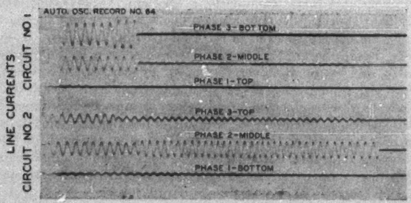

Fig. 3—Double-Circuit Outage Due to Lightning

No. 1 circuit—13 cycles to clear
No. 2 circuit—46½ cycles to clear
Glen Lyn-Roanoke 132-kv double-circuit line, September 1, 1932—1.32 p. m.

During the early part of 1932 an automatic oscillograph of the latest type was installed at Glenlyn and connected so as to measure the 6 line currents on the double-circuit Glenlyn-Roanoke 132-kv line. Records were obtained of all outages during the past year, and some of these records should prove of interest.

Fig. 1 shows a single-circuit outage in which a flashover occurred on the top conductor of circuit No. 1. It will be noted that there was no follow-up current on any of the other conductors. It would appear that a direct stroke to this top conductor might explain this outage.

Fig. 2 shows a single-circuit outage due to lightning, in which the follow-up current existed only in the bottom conductor of circuit No. 2. This flashover can reasonably be accounted for by either a direct or induced lightning stroke.

Fig. 3 shows a double-circuit outage in which both circuits evidently flashed over at about the same time. This flashover involved the middle conductor of both circuits and the bottom conductor of circuit No. 1. This particular flashover can be accounted for by an induced lightning stroke, but it is not so readily accounted for if a direct stroke to the system is assumed.

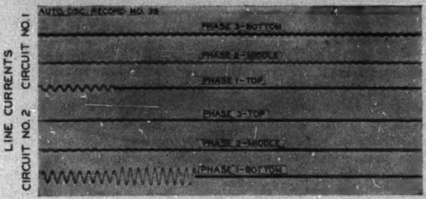

Fig. 2—Single-Circuit Outage Due to Lightning

No. 2 circuit—18½ cycles to clear
Glen Lyn-Roanoke double-circuit line (132 kv), July 14, 1932—5.07 p. m.

In Fig. 4 is shown another outage that eventually involved both circuits. The interesting point brought out by this oscillogram is that the follow-up current which started on the middle conductor of circuit No. 2 cleared before a short circuit took place on the top conductor of circuit No. 1. Some ¾ of a cycle elapsed between the time the arc went out on circuit No. 2 and started on circuit No. 1. In this particular case we have no way of definitely knowing whether the second flashover resulted from the first, or whether there were actually two separate and distinct lightning discharges. However, it would appear that the trouble on the top conductor of circuit No. 1 was a direct result of the trouble on the middle conductor of circuit No. 2 and not initiated by the original flashover.

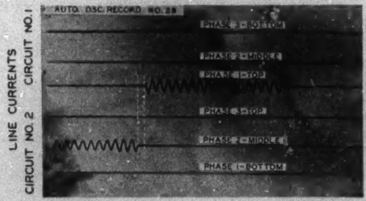

Fig. 4—Double-Circuit Outage Due to Lightning

No. 2 circuit—12 cycles to clear
No. 1 circuit flashed over ¾ cycle after circuit No. 2 cleared
Glen Lyn-Roanoke double-circuit line (132 kv), July 6, 1932—1.32 p. m.

A physical inspection of the line or a report based on relay targets would, of course, list this as a double-circuit outage. Furthermore, it would probably be explained as a direct stroke to the top conductor and such an explanation would, of course, be incorrect.

In general, it has been found that the oscillographic records agree with relay targets as to the location of outages with respect to phases, and that the totalized outages with respect to phases are in fairly close agreement as recorded by the oscillograph and by tower-climbing inspection reports. However, by proper use of the oscillograph all possibility of doubt can definitely be removed and a positive record obtained of the sequence of events during the outage.

There were no double circuit outages on the Glenlyn-Roanoke line that could be attributed to an overload or unstable condition; that is, there was no evidence of an outage of one circuit resulting in a disturbance that caused the second circuit to trip. This is definitely shown by the oscillograph records obtained during the past lightning season. A study of the outages on all other double-circuit lines of the system has led us to believe that none of the double-circuit outages so far experienced has resulted from power swings or straight overloading of the second circuit due to tripping of the first.

**F. W. Peek, Jr.:** This paper contains much more fundamental information than is apparent on a casual reading. This is illustrated by referring particularly to Fig. 5. This figure shows that even when the tower footing resistance is as low as 3 ohms, one outage can be expected in every ten storms and that the lightning outages per storm increase until the footing resistance reaches 40 ohms. At higher resistances the outages do not increase. It would appear that the particular outages affected by resistance are due to direct strokes since the lower values of resistance would not reduce the efficiency of the ground wire. It is possible from these two points on the curve to get an approximate idea of the minimum and maximum values of direct stroke currents. We have found that the voltage $V$ on an insulator due to a direct stroke to the tower is

$$V = 0.8\, IR$$

where $I$ is the lightning current and $R$ the tower footing resistance.

The insulator sparkover of this line is approximately 1,200,000 kv. Therefore, the current is

$$I = \frac{1{,}200{,}000}{0.8\, R} = 500{,}000$$

Where 1 outage occurs in 10 storms, the footing resistance is 3 ohms. Therefore a maximum current of 500,000 amperes would be expected in one direct stroke to the line in 10 storms. From the other end of the scale, it follows that the minimum direct stroke current for lightning storms equals

$$I = \frac{1{,}200{,}000}{0.8 \times 40} = 37{,}500 \text{ amperes}$$

These values are very approximate, it is true, but they indicate the order of the current range of direct strokes and, incidentally, are of the same order as those obtained by direct measurements.

# Impulse and Dynamic Flashover Studies of 26-Kv Wood Pole Transmission Construction

BY A. S. BROOKES* Associate, A.I.E.E.      R. N. SOUTHGATE* Associate, A.I.E.E.      and      E. R. WHITEHEAD† Associate, A.I.E.E.

***Synopsis.**—This paper presents the results of a series of laboratory tests made with a million volt surge generator and 60-cycle high-voltage testing equipment on unit pole transmission construction now in standard usage on a large 26-kv transmission system. Actual impulse curves are given for several types of straight span pole top construction. Basic values of impulse flashovers are presented which should facilitate coordination of impulse insulation between poles of any similar transmission lines, aid in applying protective gaps, and furnish a guide to the comparative impulse strength of both present and new types of construction. Defects in present design standards and possible improvements are discussed.*

*An analysis of the factors governing the development of a power arc following impulse sparkover and corresponding experimental data showing the extent of occurrence of such arcs are presented. The paper concludes that reliance upon air or wood separations within the usual physical limits to prevent lightning outages will be unsatisfactory, and discusses the application of protective measures.*

* * * * *

## INTRODUCTION

THIS study has been made on the 26-kv wood pole transmission construction of the Public Service Electric and Gas Company in cooperation with the Westinghouse Electric and Manufacturing Company. The objects of this investigation were to secure adequate data to estimate the relative lightning performances of present and proposed construction.

## EQUIPMENT

The series of tests was made by subjecting actual unit pole assemblies to impulse and 60-cycle voltages, separately and simultaneously. The test equipment consisted of a million volt surge generator[1] and a 60-cycle, 750-kv test set.

## TEST WAVE

For all tests a 0.5-0.75/60 positive wave was used. No corrections were made for barometer or humidity.

In plotting volt-time curves[5] of combinations involving wood, the a-c flashover voltages sometimes exceeded the impulse. This irregularity is ascribed to the variation in wood specimens, the difference in path of the impulse arc at long and short time flashovers; and to the difference in path of the impulse and dynamic flashovers. However, as the 60-cycle datum point is taken on the steep front of the wave, a large variation in this value will change the impulse curve but slightly.

In applying the volt-time curves given in this paper, the regions below one microsecond should be considered approximate since the measuring circuit may have distorted the wave front slightly and the a-c flashover values may be erratic.

## 60-CYCLE AND IMPULSE TESTS ON COMPONENT PARTS OF WOOD POLE TOPS

It was desired to obtain some simple basic means of comparing pole top flashover values. Unfortunately preliminary tests showed that when wood is involved, no workable relationship exists between impulse and a-c values. Accordingly impulse tests were made on the component parts of pole top assemblies so that the data secured could be used to compare other pole tops.

Sixty-cycle flashover tests were made on wooden crossarms and on each component assembly. Fig. 1 shows the range of values for dry seasoned arms, for unseasoned arms and for wet arms, with their averages.

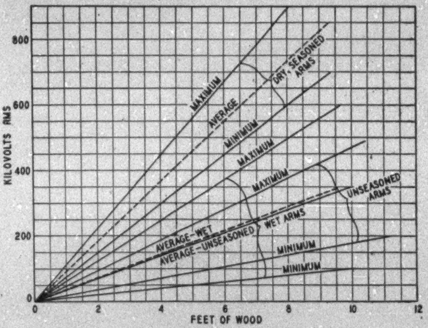

FIG. 1—60-CYCLE FLASHOVER VALUES FROM TESTS ON DRY, WET, AND UNSEASONED FIR CROSSARMS

The results on crossarms in combination with porcelain are given with the impulse curves.

These 60-cycle crossarm test results may be summarized as follows:

1. Both unseasoned and wet wood have negligible a-c insulation strength.
2. Creosoting does not appreciably alter the 60-cycle insulation of wood.
3. The 60-cycle values vary so greatly for different specimens and conditions that they give no indication of the impulse strength.

In securing volt-time impulse curves, one terminal was grounded. This method gives actual impulse flash-

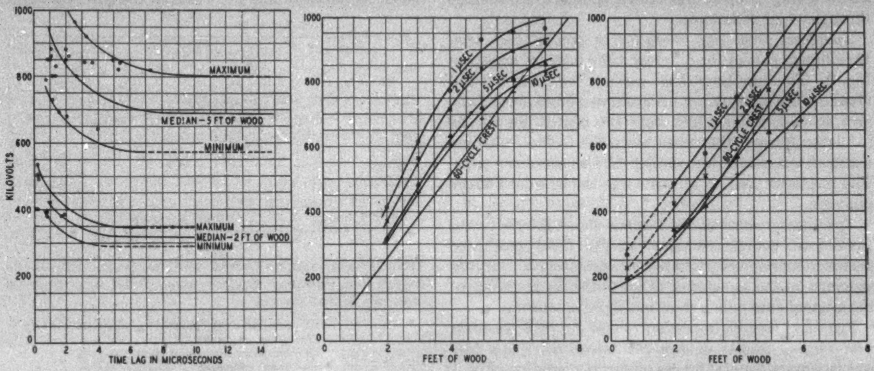
over voltages when the arc is from any conductor to a ground but the values give only comparative impulse strengths for flashover between conductors. For the latter case, it would be necessary to consider, among other factors, the induced voltage on the second conductor.

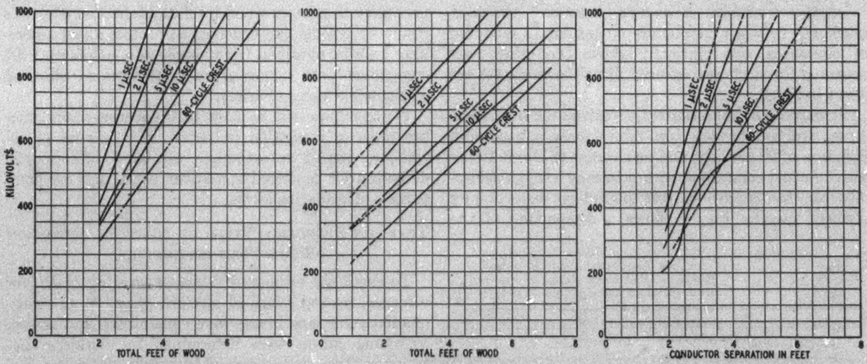
No data are here given for sparkovers in midspan, as adequate information on air breakdown is available. The following pole top component parts were considered essential.



Volt-time curves for fir crossarms

Breakdown curves for fir crossarm alone

Breakdown curves for fir crossarm and one 45-kv porcelain pin insulator



Breakdown curves for 2 insulators mounted on the same arm, spacing varied

Breakdown curves for 2 insulators mounted on a 10-ft arm, with various brace lengths (see Fig. 3)

Breakdown curves for 2 insulators each mounted on a separate crossarm, the crossarms being separated vertically

FIG. 2—TYPICAL VOLT-TIME CURVES AND BREAKDOWN CURVES FOR COMPONENT PARTS OF WOOD POLE TOP ASSEMBLIES

*Various lengths of fir crossarm.* The crossarms used were standard creosoted fir arms of 4 by 5 in. cross section which had been used for several years. The electrodes consisted of two metal bands around the crossarm. Fig. 2 shows typical volt-time curves, and breakdown curves for different time lags. It will be noted that there is a wide scattering of points, the extreme points in the volt-time band being nearly 20 per cent from the median curve. These erratic results are explained by the non-homogeneity of the wood and variation in physical characteristics of the different specimens tested, such as moisture, aging and type of grain. Considerable variance was found in tests on a single arm with all external conditions constant.

Investigation of the comparative impulse strengths of wet and dry, freshly creosoted and untreated, new and well seasoned, and of splintered and unscarred arms failed to reveal any measurable trend due to these causes.

*Pole tests.* Some tests made on a section of wood pole alone between electrodes of wire banding showed such a wide variance between individual poles that the tests were not extended, particularly since values are available.[3,6] Impulse tests on a badly checked and weathered chestnut pole showed a sparkover voltage of about 90 kv per ft at 5 microseconds. The impulse spark occurred within the wood fibers and oscillograms showed a slow voltage drop at breakdown, similar to a discharge through a high resistance.

*Sparkover from one conductor to ground over arm.* Breakdown curves for different time lags are shown in Fig. 2. The impulse voltage was applied to an 8-ft rod mounted on an insulator. A grounded band around the arm at various distances from the center line of the insulator formed the other electrode. The volt-time curve shows scattering similar to the crossarm tests. The insulator used on all tests was the standard 45-kv pin type.

*Sparkover from conductor to conductor on the same arm.* Breakdown curves are shown in Fig. 2 for sparkover between conductors mounted on insulators at varying spacings on the same arm. Due to the air breakdown, the original data points show but slight scattering.

*Sparkover between conductors spaced 8 ft on a crossarm with varying lengths of arm short-circuited.* This test was to simulate metal braces of varying lengths. Fig. 3 shows the test arrangement and Fig. 2 gives the breakdown curves.

*Sparkover between conductors separated vertically.* Sparkover between conductors on insulators mounted on crossarms, one vertically above the other, was measured for varying spacings. Breakdown curves are shown in Fig. 2.

Comparison of impulse strength calculated from these curves and actual pole top values show a maximum deviation of 20 per cent and an average of about 10 per cent. Actual conditions on a pole may vary considerably from test conditions, due to gradient distortion by adjacent metal. Fig. 4 shows a comparison of the measured values on a double-armed pole with those estimated from the component part curves. Since the sparkover voltages for double arms are about 7 per cent higher than for single arms, the agreement will, in general, be closer than indicated.

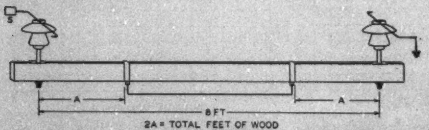


FIG. 3—TEST ARRANGEMENT FOR TWO 45-KV PIN INSULATORS MOUNTED ON A 10-FOOT FIR CROSSARM WITH METAL STRAPS IN CENTER SIMULATING VARIOUS LENGTH CROSSARM BRACES

Wood poles, crossarms, and particularly wooden braces shatter considerably under impulse sparkover. With the available surge current, no appreciable increase in shattering due to bolts or hardware was noticed, although with the high current in lightning strokes, the establishment of multiple paths may cause such an effect. Tests show a lower sparkover voltage through wood fibers than for surface flashover, thus increasing the tendency to splinter. With properly designed gaps, the path of the spark may be confined to the air as shown in Fig. 6. Tests on the gap clearances necessary to protect wood insulation checked Melvin's results.[3] Needle gap spacings to protect given assemblies may be obtained from needle gap curves and the component part curves given in this paper, allowing a reasonable factor of safety.

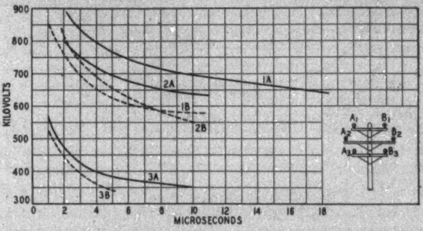

FIG. 4—COMPARISON ACTUAL AND ESTIMATED FLASHOVER CURVES FOR VERTICAL CONFIGURATION POLE WITH DOUBLE ARMS AND METAL BRACES

Curve 1A—-Flashover from phase $A_2$ to phase $B_2$
1B—Same, estimated
2A—Flashover from phase $A_3$ to phase $A_3$
2B—-Same, estimated
3A—-Flashover from phase $A_3$ to phase $B_3$
3B—Same, estimated

It was impractical to make tests covering many combinations of insulation in series. The curves given, while necessarily not complete, will be of chief value in designing for preferred sparkover paths and for comparison of insulation levels.

## TESTS ON STANDARD TYPES OF 26-KV TRANSMISSION WOOD POLE ASSEMBLIES

To check the estimated values of pole top sparkover voltages, several types of straight span, 26-kv transmission poles now in use were constructed and tested. Volt-time curves were determined for flashover between any two conductors and for conductor to grounded guy sparkovers, when within range of the surge generator. As the component part curves were found reasonably accurate for estimating, tests were not made on angle or pothead poles. In all tests 8-ft copper rods simulated the conductors. Only representative values are given as space does not permit inclusion of the complete impulse curves for each sparkover path. Table I gives the dimensions of all standard pole tops tested.

Fig. 5 presents a summary of the results from all pole tops tested. It will be noted that wooden braces on the horizontal configuration pole do not improve the line-to-line insulation. On the triangular configuration pole,

TABLE I—STANDARD 26-KV LINE POLE TOP DIMENSIONS FOR USE WITH FIG. 4

| Configuration | Crossarms | Crossarm vertical spacing | Braces | Conductor spacing in inches $A_1 - B_1$ | $A_2 - B_2$ | $A_3 - B_3$ |
|---|---|---|---|---|---|---|
| Double-circuit Triangular | One 7 ft<br>One 10 ft | 32 in. | Metal—<br>Spread—60 in.<br>Drop—18 in. | 76 | 112 | 40 |
| Double-circuit Vertical | Two 7 ft<br>One 10 ft | 42 in. | Same | 76 | 112 | 76 |
| Single-circuit Horizontal | One 10 ft | | Same | $\left(\frac{A_1 - A_2}{36}\right)$ | $\left(\frac{A_1 - A_2}{76}\right)$ | $\left(\frac{A_1 - A_3}{112}\right)$ |

about 40 per cent increase in line-to-line impulse strength is gained by using wooden braces. Due to the equilateral spacing, nothing can be gained by increased arm separation. Wooden braces on the vertical configuration pole about double the line-to-line insulation. At 60-in. arm spacing the minimum line-to-line insulation becomes as great as can be secured, due to the fixed clearances across the 7-ft arm.

The lowest line-to-ground sparkovers for various guy positions on a pole using standard insulator spacing on a 7-ft arm are also shown in Fig. 5. It can be seen that small porcelain guy insulators add very little insulation and also that guying to the double arm through-bolt is very undesirable. When line stresses permit, the guy should be attached several feet below the bottom brace. When guying to adjacent poles, as great a distance as possible should be left between the point of attachment and any ground.

## POWER FOLLOW TESTS

To make a comprehensive study of the development of a power arc following an impulse breakdown would require controlling numerous factors among which are:

1. Magnitude of the 60-cycle power voltage.
2. Angle on power voltage at which the impulse breakdown occurs.
3. Length of breakdown path.
4. Magnitude and duration of impulse current.
5. Breakdown through air or solid dielectric.
6. Voltage recovery characteristic at flashover point.
7. Short-circuit current available.

In this investigation, data were sought on factors 1 to 5 inclusive.

Fig. 7 shows the test circuit. The tripping potential could be varied in 30 degree steps leading or lagging the crest voltage of the supply. The short-circuit current at 26.4 kv was limited to 24.2 rms amperes symmetrical current. The voltage was controlled by a regulator in series with the 350 kva, 4,800/30,000-volt transformer. An arrester and inductance protected the transformer winding. The gap electrodes were copperweld rods, ½ inch diameter. Maximum consistency in results was obtained by energizing the master trip gap and then charging the surge generator.

For a given tripping angle, the gap was progressively increased until the maximum distance at which power would follow was reached. Fig. 8 shows the results of several hundred tests at 26.4 kv at gap spacings from 3 to 50 inches. The height of each rectangle indicates the range of variation of the follow distances, those greater than the upper limit not permitting a power arc, while those less than the lower limit resulting in an arc on every trial. The rectangle base gives the probable range of angles, taken from osiso records, at which the impulse breakdown took place.

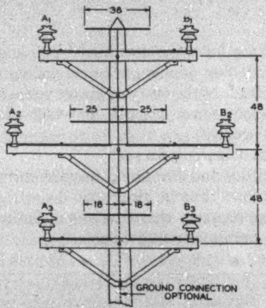

FIG. 6—VERTICAL CONFIGURATION POLE TOP WITH GAP TO PREVENT WOOD FROM SHATTERING

All dimensions in inches: for crossarm and brace dimensions see Table I

Fig. 9 shows the effect of varying the magnitude of the power voltage with a constant tripping angle. The linear characteristic shows that other factors involved probably remained unchanged.

*Breakdown through wood.* Testing with the tripping connections to give maximum air power follow, wood was subjected to breakdown with an air gap in series to prevent continuous application of the a-c voltage to the wood. For surface breakdown, the power follow distance was substantially the same as in the air gap tests. When any part of the breakdown was within the body of the wood for a minimum of 12 inches, power follow was prevented. In many cases a shorter wood path sufficed, but the results were variable for lengths under 12 inches.

The gradient necessary to maintain a discharge in a closely confined path is greater than in open air. The impulse arc is thus quickly deionized and a power arc prevented by confining the discharge within wood fibers. Transmission line inspections have revealed many instances where crossarms and pole sections have been splintered by lightning without resulting outages.

Using various means of confining the impulse breakdown within wood, the effectiveness of wood as a deionizing agent was demonstrated. Thirty discharges of 6,000 amperes between nails driven in the center of a 4 by 4 in. cross section gave no power arc, but shattering increased with smaller cross sections. Trial installations of the wooden block protector are in service and use of them in the future will depend on the operating record obtained. Design details of the blocks will require further field experience, but will probably be similar to those in Fig. 10. Application will be similar to that of the deion protector.

Another deionizing device for use in series with an air gap consisted of a fine wire, over 12 inches long, clamped between two pieces of wood. The breakdown potential is that of the series gap. Later tests with this device connected between phases of a 22-kv line showed a discharge of the line capacitance and restoration of potential without passage of power current. This device has possibilities as a back-up relief gap for substations.

*Interpretation of results.* An impulse breakdown results in a highly ionized path of small cross section. The inductance of the path being negligible, the line capacitance instantly begins to discharge. Load current transfer into the arc will be negligible during and immediately following the impulse breakdown. If the arc is to continue, the arc voltage must become and remain lower than that of the line during this brief period. Fig. 11 shows the transient relations existing during the discharge of line capacitance. The voltage to maintain the arc rises rapidly after the impulse ceases. If the arc voltage $e_a$ rises higher than the instantaneous circuit voltage, $e(t)$, a condition dependent upon the point of breakdown on the 60-cycle wave and the nature of the path, the arc is effectually broken; the entire process taking from 200 to 400 microseconds.[7]

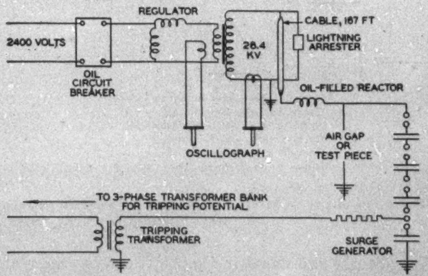

FIG. 7—DIAGRAM OF CIRCUIT USED FOR POWER FOLLOW TEST

If power current flows, it generally follows a transient half cycle which depends on the circuit reactance, the arc voltage and the point of breakdown on the 60-cycle wave. The fate of the arc is decided at the first current zero and conditions at this time depend upon the current transient immediately preceding. The problem is essentially that of the extinction of a long a-c arc in air, discussed by Slepian.[9]

Fig. 12 shows the current transient for impulse breakdown at 30 and 150 degrees on the voltage wave. The instantaneous voltage tending to initiate the arc is the same in each case, but the ensuing current transients differ greatly. $I_1$ has a high maximum and decreases rapidly near zero, while $I_2$ has a low maximum and decreases slowly near zero. At zero for $I_1$ the arc path must withstand a transient recovery voltage of about 2 $e_1$, while, at zero for $I_2$, it must withstand only about 2 $e_2$.

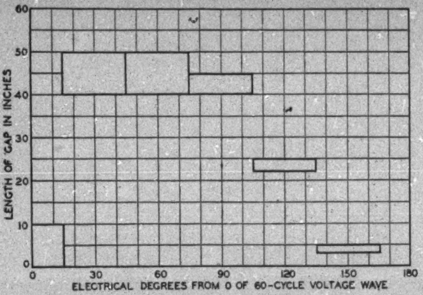

FIG. 8—VARIATION OF POWER FOLLOW DISTANCE WITH POINT ON THE 60-CYCLE VOLTAGE WAVE AT WHICH IMPULSE BREAKDOWN OCCURRED

At current zero, the deionization of a long arc in air may be considered as due to diffusion of ions from the high temperature core of the positive column to the cooler boundary regions surrounding the arc and their subsequent recombination in this region. If this explanation be accepted, a qualitative expression for the breakdown gradient of the arc space after current zero is:

$$X = \frac{B}{a\, n_0} \qquad \epsilon^{\frac{c}{a} t} \tag{1}$$

where $x$ = breakdown gradient in volts per cm
$t$ = time after current zero
$a$ = radius of arc section
$n_o$ = ion density at current zero
$B, c$ = constants

Since the cross sectional area of the arc lags behind the decreasing current, its value at current zero will be greater, the higher the rate of current decrease. It is evident from Fig. 12 that $I_1$ requires a much larger arc section at maximum current than does $I_2$. Near current zero $I_1$ decreases more rapidly than $I_2$. These factors give a much smaller arc section at current zero for $I_2$ than for $I_1$. Equation (1) indicates this variation in arc section is mainly responsible for the variation of $X$.

Thus $I_1$ results in a low arc breakdown gradient and a comparatively high recovery voltage which permits long power arcs after impulse flashover, the opposite being true for $I_2$.

In the region near voltage zero, the power voltage was insufficient to initiate the current flow except for the short spacings noted. Since in these tests no capacitance discharged through the impulse path, the rate of current flow was determined by the difference between the instantaneous arc and circuit voltages immediately following the impulse current, divided by the circuit inductance. Near voltage zero the arc voltage rises above the circuit voltage and the transient current flows only for short gap spacings.

Equation (1) also shows that for the actual transient currents met in practise the arc breakdown gradient curve will have a much lower initial value, and will increase much more slowly than the low transient test current. Therefore, if the conditions necessary for the establishment of the first transient half cycle are fulfilled, the arc in air will not extinguish at the first current zero. Thus the factors determining the occurrence of a power arc following lightning sparkover on a transmission line must be found in the fast transient phenomenon indicated in Fig. 11.

On a transmission line, the discharge of the line capacitance furnishes a current to the arc much greater than the initial test current here described, hence it may easily be seen how very long follow arcs can occur in practise.

A few tests on the effect of low or high impulse current during breakdown revealed no satisfactory definite trend.

## GENERAL DESIGN PRINCIPLES

The data presented can be used to design a pole line which should give adequate lightning performance and meet local operating requirements. The following factors should be considered in the design of new pole lines:

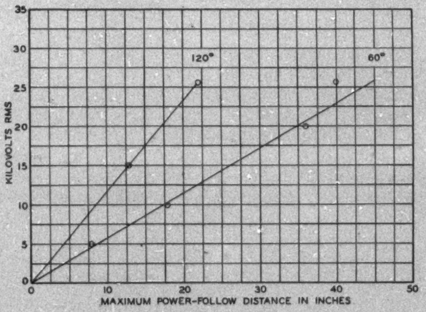

FIG. 9—VARIATION OF FOLLOW DISTANCE WITH POWER VOLTAGE FOR GIVEN PHASE ANGLE

1. When the importance of a line economically justifies it, improved lightning performance may be secured by the judicial use of wood and increased clearances; or application of a dynamic arc suppresser such as the deion fiber tube arrester or a device employing the suppressing

qualities of wood. Some type of protector is indicated as the most efficient method of accomplishing this purpose, since other data show that the prevention of the dynamic follow arc by increased clearances is not to be relied upon.

2. Whichever design is followed, the pole top should be so proportioned that the lightning sparkover will occur through the air, or through the protector rather than through the crossarms or wood braces.

3. When no protectors are used, it will be advisable to make the insulation level of the line as high as possible, and also of uniform insulation between the several types of poles, in order to minimize the number of flashovers. Care, of course, should be taken to provide adequate protection for equipment at the line terminals, and for any intervening cable sections.

4. When the system conditions make a ground fault preferable to one from line to line, it is desirable to make the voltage required for flashover to ground less than that required between lines.

ELECTRODE TUBES SLIPPED ON

FIG. 10—TWO SUGGESTED FORMS OF WOODEN BLOCK PROTECTORS FOR 26-KV OPERATION

5. In the case of two-circuit lines, it is desirable to have flashovers between circuits take place between the same phases, as then no interruption will result.

One line embodying these principles has been constructed by the Public Service Electric and Gas Company. It uses the deion fiber tube protector, one per phase, on a two-circuit pole line in the vertical configuration. Due to special maintenance requirements the top and bottom crossarms are 10 ft and the middle 14 ft, spaced 4 ft on the pole. The protectors are placed on every fourth pole which has metal crossarm braces, the intervening poles having wooden cross arm braces. Care has been taken to keep the angle pole insulation on a high level and to install protectors on adjacent poles.

## CONCLUSIONS

1. Wood is an effective insulator for lightning voltages and should be fully utilized in transmission line design when increased impulse insulation is desired.

2. The net flashover voltages (one electrode grounded) of wood and porcelain combinations of simple pole tops can be estimated within 20 per cent from the data presented.

3. Seasoned wood has high 60-cycle insulating value for short times of voltage application when dry, but its insulation value is much impaired with even a slight increase in moisture content. Creosoting has no appreciable effect on these properties.

4. Creosoting or moisture has no appreciable effect on the impulse sparkover values for wood.

$Z_s$ = LINE SURGE IMPEDANCE

FIG. 11—INITIAL FAST TRANSIENT SUPPLYING CURRENT TO THE BREAKDOWN PATH BY DISCHARGE OF THE LINE CAPACITANCE

5. Measurements of 60-cycle arcovers on wood pole tops cannot be used as an accurate indication of the impulse sparkover voltages.

6. Tests indicate that the occurrence of the dynamic arc following sparkover cannot be eliminated by increased clearances within practical design limits, for the operating voltages under consideration.

7. The fact that the dynamic arc was prevented from following the path of an impulse arc when confined within wood fibers offers interesting possibilities for field experiments.

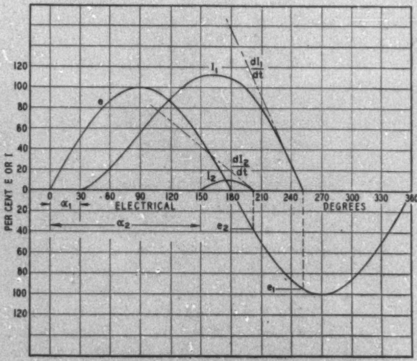

FIG. 12—SLOW TRANSIENT CURRENT THROUGH THE ARC

8. Damage to pole tops by wood splintering can be prevented by application of a suitable gap having a breakdown voltage less than that shown to be required to spark over the insulator and wood.

9. Data are now available for designing a wood pole line with almost any practical degree of lightning reliability, economic considerations being the limiting factor.

### ACKNOWLEDGMENT

The authors wish to express their appreciation to Messrs. A. W. Gothberg and J. J. Torok for their invaluable assistance in planning and carrying out the tests. The suggestions of Messrs. R. N. Conwell, H. K. Sels, L. W. Codding and G. E. Dean, and the field assistance of Mr. E. E. Kussmaul, Mr. F. A. Brownell and the Metuchen Laboratory personnel assisted greatly in this work.

## Discussion

**H. K. Sels:** At present the more or less definite conclusions stated in the paper are justified by test results only, although mention was made of a line using the deion fiber tube protector and installations of wooden block protectors on the Public Service Electric and Gas Company system. It is the purpose of this discussion to present the interesting features of these installations.

The line is of vertical configuration and, due to special maintenance requirements of keeping 1 circuit in service at all times, has two 10-ft and one 14-ft crossarms, spaced 4 ft apart on the pole as shown in Fig. 1. As the span length is about 100 ft, it is believed that adequate protection will be obtained from protectors installed on every fourth pole which has metal crossarm braces. Protectors are also installed adjacent to poles with potheads, of which there are 4 sets on each circuit, and also next to angle poles. Unprotected poles are unguyed and equipped with wooden crossarm braces giving flashover values, phase to phase, well in excess of 1,000 kv. A large difference in insulation level exists between the poles with protectors flashing over at about 200 kv to ground and the intermediate pole insulation which is in excess of 1,000 kv. An effort was made to have all of the driven ground resistances less than 20 ohms and those adjacent to pothead and angle poles less than 2 ohms. Megger readings after installation showed that all resistances were less than 17 ohms and 85 per cent less than 8 ohms.

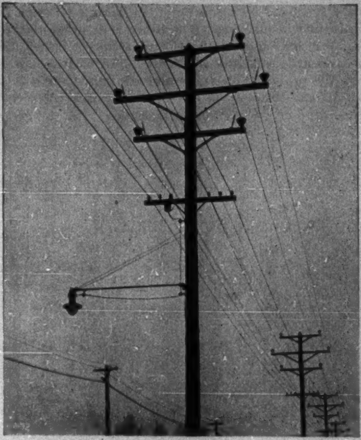

FIG. 1—PROTECTED POLE USING DEION FIBER TUBE PROTECTORS AND METAL CROSSARM BRACES

Second pole unprotected with wooden crossarm braces

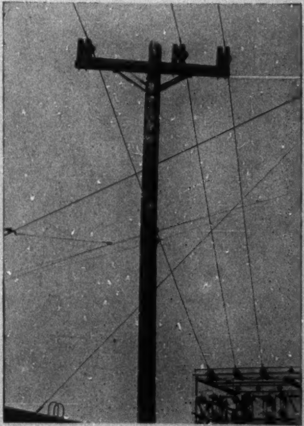

FIG. 2—PROTECTED TERMINAL POLE USING WOODEN BLOCK PROTECTORS WITH PIN ELECTRODES

In order to provide some measure of lightning protection for two small outdoor substations, each fed by two incoming lines, 4 installations of the wooden block protectors have been made. These protectors were installed on each pole nearest the substation, one installation similar to each type shown in Fig. 10 of the paper being used at each substation. The wooden blocks with the pins in the end are mounted on a separate crossarm under the line conductors, double blocks being used in case one should be shattered by a nearby direct lightning stroke. Fig. 2 illustrates this installation. The other type of protector with turned down ends and tubular electrodes was mounted directly on the crossarm with the conductors. In each case the gap between the protector electrode and the conductor is 3 inches and the distance through the wood is 9 inches. The wood is untreated fir, 5 in. by 5 in. in cross section. The lower end of the protectors was connected to a driven ground and a 50 ft to 75 ft tie to the substation ground which is under 2 ohms resistance. The value of impulse current to which the protectors will be subjected is limited by the line insulation and will be less than the 6,000 amperes at which the blocks have been tested without appreciable shattering. This is believed to be adequate to protect the substation bus which is insulated to the 34.5-kv voltage class, without any appreciable effect on the line operation.

Unfortunately, all this work was completed so late in the 1932 lightning season that no operating results were obtained but it is hoped that these installations, together with others, will ultimately justify the conclusions drawn from the tests and presented in the paper.

# Operating Experience With Wood Utilized As Lightning Insulation

BY H. L. MELVIN*
Fellow, A.I.E.E.

**Synopsis.**—*Operating experience with a large number of lines of various types, utilizing wood as lightning insulation, has demonstrated that ordinary woods have considerable insulation strength for lightning voltages, and that wood can be used to advantage in combination with other measures for improving the lightning performance of lines. The analyses have contributed materially to the present general conclusion that lightning strokes terminating on conductors and structures are responsible for the majority of lightning flashovers, at least on the higher-voltage lines; also that direct strokes must and can be coped with. The methods offering the greatest promise at present are; (1) diverting the lightning strokes from the conductors and conducting the lightning currents to earth without permitting flashover to the power conductors; (2) draining the lightning from the power conductors through fast operating dynamic follow current interrupting devices, thus avoiding insulator flashovers; and (3), a combination of these two methods.*

*High lightning insulations alone are not generally effective in reducing the number of lightning tripouts of lines, though in the lower-voltage ranges, some decrease in the probability of dynamic current following the lightning arcs may be realized.*

## INTRODUCTION

WITH the active initiation of lightning investigations a few years ago, the importance of having data on the impulse characteristics of insulations, and of a better understanding of the use of insulations available in construction, came to the fore. Wood had long been recognized as having insulating properties, indicated by application in line construction, use in the manufacture of apparatus, and from laboratory tests. To obtain measures of the impulse strengths of various amounts and kinds of woods as they might be used in line construction, and under varying conditions of contamination and moisture, a series of tests were conducted early in 1928 which were presented to the Institute by the author at the Pacific Coast Convention in 1929.[1] The results of these tests held considerable interest, inasmuch as relatively high insulation strengths were indicated for lightning voltages for practically all of the ordinary kinds of woods, under practically all expected service conditions. It also was indicated that wood could be protected from damage by the use of bypass protecting air gaps. Furthermore, it seemed practicable to materially increase the lightning insulation strengths of wood lines by rather simple and inexpensive methods. Accordingly, ideas developed from these data were applied in an experimental manner in the construction of a number of lines, to determine from actual experience what service improvements might be realized, and for the purpose of contributing to the lightning research results.

These transmission lines under trial, totaling approximately 1,300 miles and located on several systems, are representative of most of the severe lightning conditions to be met with in the United States. Space does not permit nor would interest justify describing and tabulating the results in detail. It is believed, therefore, that it will suffice to show several typical illustrations with brief descriptions of the construction and present only the more important results and the pertinent conclusions drawn from the carefully collected data and observations. With knowledge concerning the mechanism and magnitudes of lightning still incomplete, it is of course impracticable to make the statements very positive or final.

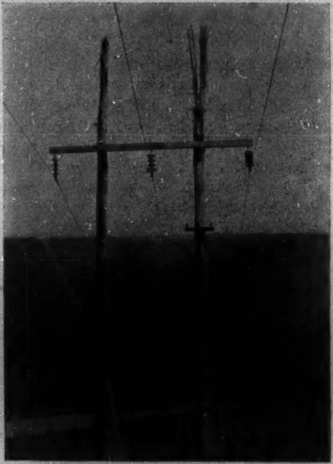

FIG. 1—LIGHTNING DAMAGE TO UNPROTECTED WOOD STRUCTURE
(Photographed after temporary repairs)

## DESCRIPTION OF EXPERIMENTAL CONSTRUCTION

When it is considered that lightning voltages are of sufficient magnitude to break down great distances through air, and strokes terminating on wood structures will do damage as illustrated by Figs. 1 and 2, little hope

---

can be entertained of stopping lightning with insulation alone. However, it was thought that possibly some lightning of lesser voltage and current magnitudes (including induced voltages of 50 to 75 kv per ft of conductor height and possibly mild branch strokes) might appear on lines and be held with high insulation, thus reducing line tripouts.

FIG. 2—BASE OF FIG. 1 STRUCTURE

The first trials consisted of simply increasing the insulation of the three phases to ground by substantial amounts. Fig. 3 illustrates a 66-kv line of the Kansas Gas and Electric Company, with 9-ft guy insulators and 3-ft 8-in. protecting gaps in multiple to ground, mounted on the pole. Initially, unprotected 7-ft gaps between bands wrapped around the poles were used on all structures, similar to those illustrated in Fig. 7. Pole gap damage was so severe, however, that the protecting horn gaps were later added across 10-ft pole gaps. Frequently from three to six consecutive poles were flashed by what was probably a single lightning discharge. Surge voltage recorders were connected to this section of line for one and one-half seasons before, and three and one-half seasons after, the guy insulators were installed.

Two 66-kv lines of the Pennsylvania Power & Light Company were equipped with 9-ft wood guy insulators with protecting horn gaps mounted on the insulators. About one-third of the guy insulators were of the type illustrated by Fig. 6 with protecting gaps of 6 ft 6 in. and the others were similar to those shown in Fig. 3 with 3-ft 7-in. protecting gaps. Surge voltage recorders were connected to a line of similar construction except for the guy insulators for two seasons and to one of these lines for one season.

Several H-frame, 110-kv lines of the Arkansas Power & Light Company, Louisiana Power & Light Company, Mississippi Power & Light Company, Carolina Power & Light Company, Tennessee Public Service Company and the Compania Nacional de Electricidad, Mexico, also some 66-kv construction of the Carolina Power & Light Company, employed 18-ft to 24-ft guy insulators. Figs. 4, 7 and 10 are illustrative of the construction. Protection for the guy insulators on all of these lines was provided by gaps mounted on the poles.

On the first line with two 9-ft guy insulators in series, a pole gap was used of 13 ft 6 in. between bands wrapped around the poles, as shown by Fig. 7. On all subsequent construction, protecting horn gaps were applied. For the lines employing two 9-ft or one 18-ft insulator the protecting gaps were 7 ft 2 in. across 20 ft of pole, with a clearance of 3 ft 6 in. between the tips of the horns and the wood. On a line with two 12-ft guy insulators, the protecting gaps were 9 ft 3 in. across 26 ft of pole with a clearance to the horn tips of 4 ft 6 in.

Guy insulator and pole gap protection has been accomplished with the above protecting gap dimensions in a very high percentage of the cases. On the 50-mile line of the Tennessee Public Service Company with two 12-ft guy insulators, where some damage was experienced, the guy anchor rods were connected to the pole butt grounds, also, one-half of the gaps were shortened to 8 ft and one-half to 7 ft. On a line of the Louisiana Power & Light Company with 18-ft guy insulators, the protecting gaps were shortened to 5 ft 9 in. These changes have practically prevented further damage.

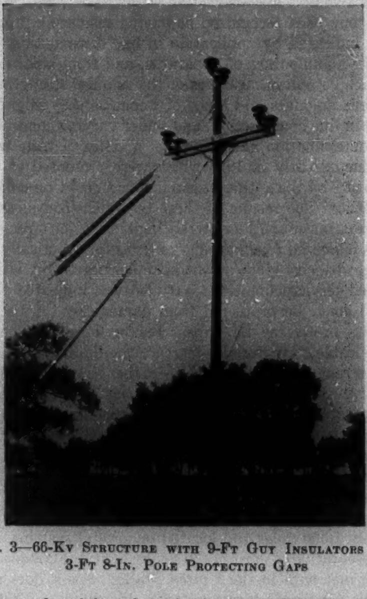

FIG. 3—66-KV STRUCTURE WITH 9-FT GUY INSULATORS AND 3-FT 8-IN. POLE PROTECTING GAPS

The use of the crossarm insulation varied. On some lines the entire length was employed in order to maintain the maximum possible phase-to-phase insulation as well as to ground; on others only the end sections were bonded to the top of the protecting gaps; and in some cases, the entire arm was bonded to prevent crossarm damage.

On about one-third of the lines, the unguyed structures utilized the full pole and crossarm insulation; on another third, the amount of wood utilized was about the same on all structures and protection was provided initially for the wood; and on the balance, provision was made for the future installation of pole protecting gaps.

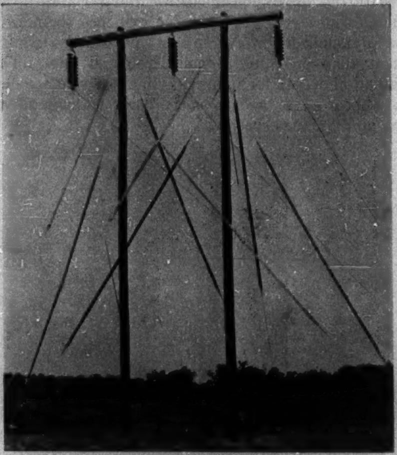

Fig. 4—110-Kv Structure with Two 12-Ft Guy Insulators and 8-Ft Pole Protecting Gaps

Other wood lines made full use of the crossarms, and adequate clearances were maintained between conductors and guys, also guy insulators were employed to a limited extent. On one of these lines on the Texas Power & Light Company system, operating at 132 kv, surge voltage recorders were connected for two seasons.

Another application of protecting gaps is illustrated by Fig. 5. Several lines on the systems of the Texas Power & Light Company and Texas Electric Service Company with conventional overhead ground wires were so equipped to utilize the insulation of the crossarm and at the same time protect them from damage by those lightning strokes which are not diverted successfully.

Figs. 8, 9 and 10 are illustrations of the so-called drainage scheme, described in a paper presented by Messrs. Pittman and Torok in 1930.[2] Here the crossarm insulation is used to provide the margin necessary for directing the lightning flashes through the dynamic follow current interrupting devices.[1] Wood guy insulators were used in the design of particular structures. It might be added that if experience indicates the probability of lightning strokes to the ends of the crossarms with resultant damage, pole bayonets sufficiently high to intercept the strokes may be advisable.

Three 110-kv lines of this design are in operation on the Arkansas Power & Light Company system and a section of 110-kv line on the Tennessee Public Service Company system. Also a very limited application of dynamic current interrupting devices has been made on distribution lines.

In the lightning diversion design illustrated by Figs. 11 and 12 the full insulation of the crossarm is utilized, also, guy insulators were employed with certain structures. The following features in connection with this 70-mile, 132-kv line of the Texas Power & Light Company may be of interest; normal span length 550 ft; approximate clearance between diverting cables and conductors at midspan 20 ft; steel lightning diverting cables bonded together at top of structure; pole butt grounds bonded together by buried wire at base; lightning insulation of nine suspension units plus 7 ft of crossarm, equivalent to about sixteen units; ground resistance values per structure (two pole butts in parallel) 40 per cent below 25 ohms, 40 per cent between 25 and 100 ohms and the balance above 100 ohms.

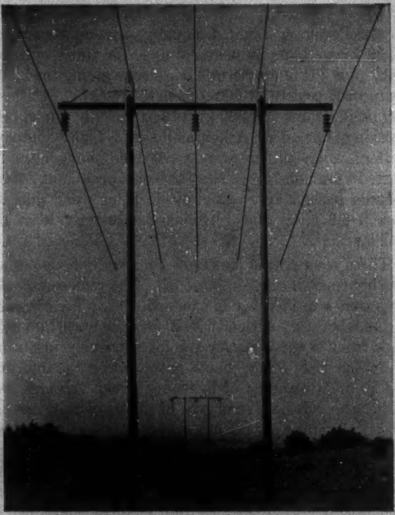

Fig. 5—66-Kv Structure with Conventional Overhead Ground Wires and Crossarm Protecting Gaps

Another use of wood in the application of lightning diverting cables is on the Wallenpaupack-Siegfried 220-kv line of the Pennsylvania Power & Light Company.[4] The diverting cables are supported by wood poles mounted on top of the steel towers and grounded through the medium of the system of guys. With this design the poles provide the insulation to prevent the lightning current from being conducted through the tower.

## OPERATING RESULTS

Surge voltage recorders on the 66-kv lines of the Kansas Gas and Electric Company and Pennsylvania Power & Light Company utilizing the equivalent of about 7 ft of wood in series with 70-kv rated pin type insulators, yielded several records of 1,000 kv to in excess of 1,800 kv. The higher value represented the recorder limit with the potentiometer ratio used, and this voltage was recorded seven times for lightning flashovers on the line ¼ to 1½ miles away from the instruments. Maximum records of approximately 600 kv were obtained for an insulator plus about 1 ft of pole or 2 ft of crossarm. Likewise on the 132-kv line of the Texas Power & Light Company, several records of 1,000 kv to 2,200 kv were obtained for nine suspension units plus 7 ft of crossarm. The stroke giving the 2,200-kv record, occurred 7,500 ft from the recorder. Cathode ray oscillograms of 4,500 kv and 5,000 kv obtained on a section of line on the Arkansas Power & Light Company system where all guys were removed, have been reported previously.[3] The strokes producing these records flashed approximately 45 ft of wood and occurred 2.3 miles and 4.0 miles respectively from the oscillograph.

These records provide ample confirmation that wood has lightning insulation strength. The maximum voltages were considerably in excess of the values obtained in the laboratory with the ¼-20 impulse wave and indicate front-of-wave flashovers for extremely fast rates of voltage rise. They should not, however, be interpreted as measurements of lightning stroke voltages, but rather the lightning strengths of the insulations, as are practically all other records which have been obtained in a similar manner. A speculation of possible interest is that if a linear relation between insulation strength and pole length holds, the voltages which could be measured across a wood structure of ordinary height would be in the order of 12,000 kv to 15,000 kv.

Few surge records of lightning voltages were obtained in the band between the flashover of ordinary line insulators and the high lightning insulations developed by the use of wood guy insulators. Also, line tripouts were coincident with practically all the high records. This indicated that few lightning voltages appeared on the lines which were not of sufficient magnitude to cause flashover. In many instances relatively low readings were obtained on some of the instruments accompanying line tripout, because in general only attenuated values were recorded on account of the spacing of the instruments.

The carefully analyzed tripout records for a number of lines equipped with long wood guy insulators and lightning flashover strengths of 1,500-kv to 3,500-kv compared with otherwise similarly constructed lines but with less than one-half of these insulation strengths, have not indicated any appreciable decrease in the number of tripouts with the higher insulation.

With the longer guy insulators and lower operating voltages however, there is some evidence to indicate that dynamic follow current may be slightly less frequent than on conventionally insulated lines. This method of attack for improving line performance does not appear advantageous as compared with the diversion and drainage schemes.

FIG. 6—DAMAGED 9-FT GUY INSULATOR WITH 6-FT 6-IN. PROTECTING GAPS

High lightning insulation in combination with lightning diversion cables properly located and grounded, somewhat as illustrated by Figs. 11 and 12, is proving very effective. The 132-kv, 70-mile Texas Power & Light Company line has not tripped out in one year of operation. There is little doubt that it has been exposed to lightning, as storms are prevalent, and a conventional 66-kv line of about the same length, in the same locality, and paralleling it for part of the distance, has been interrupted 26 times due to lightning in the same period. This should not be interpreted as a statement that the line is immune to lightning flashover, as the right strokes may not have occurred at the right points; however, the performance indicates progress and possibilities.

Records indicate two or possibly three direct strokes in two and one-half seasons to the experimental lightning diverting cable installation without line tripout on the Wallenpaupack-Siegfried 220-kv line of the Pennsylvania Power and Light Company.

The utilization of the crossarm insulation in combination with conventional overhead ground wires as illustrated by Fig. 5 is also proving effective though other design features are essential for accomplishing best results in the diversion of lightning strokes.

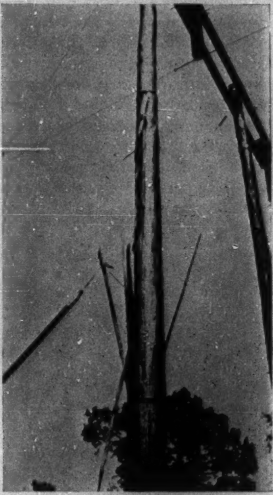

Fig. 7—Damage to 13-Ft 6-In. Unprotected Pole Gap with 18-Ft Guy Insulators

The drainage scheme likewise is showing considerable promise. Records from the three 110-kv lines of the Arkansas Power & Light Company are as follows: The 60-mile line with drain points at each structure has tripped out four times in approximately one year, three of which could be traced to failure of the arc interrupting devices or their mounting, both of which were distinctly in the development stage when installed. The 45-mile line with drain points spaced approximately one-half mile apart, and with no crossarm bonding or pole grounding wires on intermediate structures, has tripped six times in about two-thirds of a lightning season, for which failure of the devices as above can be held almost entirely accountable. With this spacing both the lightning current discharges and dynamic follow current are concentrated through one or two devices. The duties imposed on this line have been found to exceed the capacities of the devices as originally installed. The third line of 28 miles is the one on which the first experiments were conducted[2]. Drain points were spaced about 2 miles initially and then decreased to 1-mile intervals and then to ½-mile on two-thirds of the line. Its record for 2½ years since the shorter separations have been in service has been exceptionally good, only two interruptions occurring due to lightning on the drained sections.

The performance of lines on the same system with comparable construction, except for the application of the arc interrupting devices, has averaged 25 tripouts per 100 miles per year during the same periods. This would give an expected number of tripouts of 15, 11 and 5 respectively for the three lines for one season. Careful examination at the middle of the 1932 lightning season of the telltale devices employed on the 60-mile line indicated 7 successful operations of the drainage scheme.

Protection of the wood when used as lightning insulation has been accomplished very successfully and the following ratios and dimensions appear to be satisfactory for practical application.

Protecting horn gaps mounted on guy insulators or poles should have a ratio of *air gap length* to *clear wood length* of 0.35, and a ratio of *clearance from horn tip to wood* to *clear wood length* of 0.20.

Guy insulator protecting gaps mounted on the poles should span a section of pole equal to or greater than the clear wood in the guy insulators, have the same clearance ratio as above and have a ratio of *air gap length* to *clear wood guy insulator length* of 0.30.

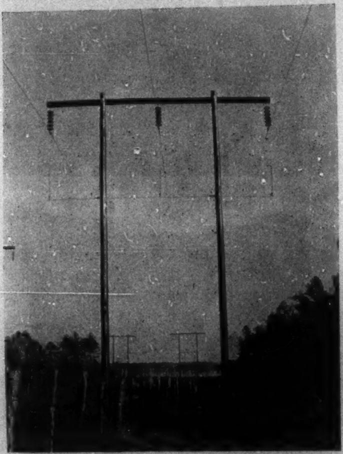

Fig. 8—110-Kv Unguyed Structure with Arc Interrupters

The uncertainties of voltage distribution with different combinations of insulators and crossarms complicate the problem of crossarm protection. Data are not sufficiently complete for offering general ratios. This much has been learned, however, from experience on about

250 miles of line for most of two lightning seasons; that with five suspension units plus 4 ft of clear crossarm with a ratio of *air gap* to *wood length* of 0.38, one arm has been damaged; similarly with five suspension units and 6 ft 6 in. of crossarm and a ratio of 0.33, one crossarm has been damaged.

On lines with conventional overhead ground wires, damage to unprotected crossarms is not generally severe. This probably is accounted for by the ground wires usually intercepting and carrying the major portion of the lightning current even though the flash may also contact the conductors in the span or at the structures.

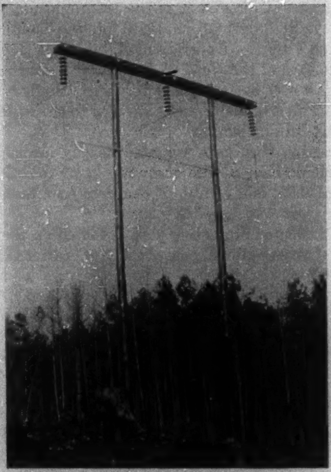

FIG. 9—110-KV GUYED STRUCTURE WITH ARC INTERRUPTERS

Sections of the wood in crossarms frequently can be used to advantage to minimize insulator damage and at the same time increase impulse insulation strengths without unduly exposing the wood to lightning damage. For years this practise has been followed, unintentionally in many instances, however improvements are possible through the proper proportioning of the crossarm wood in series with the insulators so that lightning flashes and dynamic follow current generally will not occur directly across the insulators and wood.

With the high lightning insulations obtained through the use of wood, substation protection usually is imperative. This has been accomplished quite effectively by the use of spillway gaps at the line entrances, with settings for lightning flashover at some margin below the insulation level of the station equipment and buses. These settings, types of gaps and their locations are still in an experimental stage of application, inasmuch as experience and laboratory data, as well as the determinations of insulation level requirements are not complete.

## CONCLUSIONS

Only the more important conclusions, which are considered sufficiently well substantiated for practical application in the utilization of wood as lightning insulation, are outlined. They are drawn from a large amount of experience data and results from surge voltage investigations on specially designed wood lines as well as of conventional construction, accumulated on a number of representative transmission systems operating in severe lightning territories. Further it is believed they represent the summarized thought of the engineers responsible for conducting these coordinated investigations as well as that of the manufacturing company engineers who have participated in reviews of the data during the past few years.

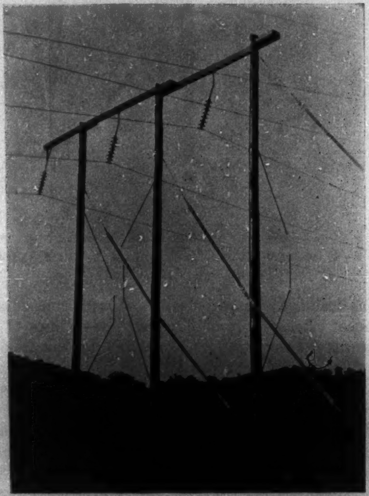

FIG. 10—110-KV ANGLE STRUCTURE WITH ARC INTERRUPTERS

1. High lightning insulation in itself, such as is practicable by utilizing wood guy insulators, poles and crossarms is not effective in materially reducing the number of lightning flashovers occurring on transmission lines.
2. The three general types of design for lines to minimize lightning influence, which at present seem most adaptable and in which the lightning insulation strength of wood can be employed to advantage, are:

a. Diversion of lightning strokes from the power conductors without permitting insulator flashover. This type of design as now conceived requires for successful operation, liberal physical dimensions and insulations as well as favorable grounding conditions, which in general make it more applicable to the higher voltage ratings. More complete data concerning the characteristics of lightning and the constants of the conducting circuits as well as the development of technique for handling the problems involved are required in order to place this method of design on better engineering and economic bases.

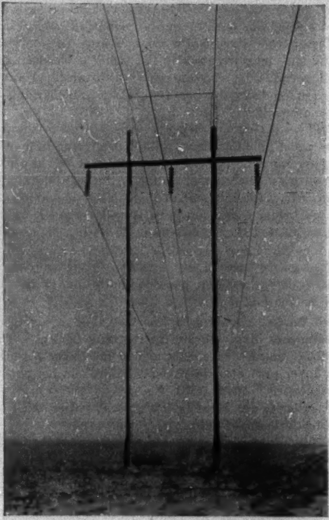

FIG. 11—132-KV STRUCTURE WITH LIGHTNING DIVERTING CABLES

b. The drainage of lightning strokes through dynamic follow current interrupting devices. This method gives promise of proving applicable and advantageous for many situations, particularly in the lower voltage ranges, also where conditions both physical and economic are not favorable for the diversion design. Its success, of course, is very dependent upon the development and limitations of the arc interrupting devices.

c. The simple design in which no particular attempt is made to avoid lightning flashover. Damage to insulators, conductors and structures can be minimized through improved design features for the line, switching and relaying, giving practical assurance that the line will return immediately to service after flashover.

3. The impulse sparkover curves presented in the earlier paper[1] can be used with a reasonable degree of confidence in estimating the comparative lightning insulation strengths of wood, combinations of insulators and wood, insulators and air gaps.

4. Caution must be observed to avoid wood burning from leakage currents, particularly where insulator contamination may occur, and in many instances such conditions may make it impracticable to utilize wood as insulation.

## ACKNOWLEDGMENTS

The cooperative and coordinated application of laboratory test and operating experience data; the systematic collection and careful analysis of line performance data; conclusions drawn therefrom; permission to review the newer resulting developments; and the material supplied specifically for this paper by the engineers who are cooperating in this practical attack upon the lightning problem, are all very much appreciated. The author wishes particularly to thank the engineers of the Arkansas Power & Light Company, Kansas Gas and Electric Company, Texas Power & Light Company, Carolina Power & Light Company, Tennessee Public Service Company, Pennsylvania Power & Light Company, Texas Electric Service Company, Louisiana Power & Light Company and Compania Nacional de Electricidad, Mexico, as well as associates in Electric Bond and Share Company. In many instances the

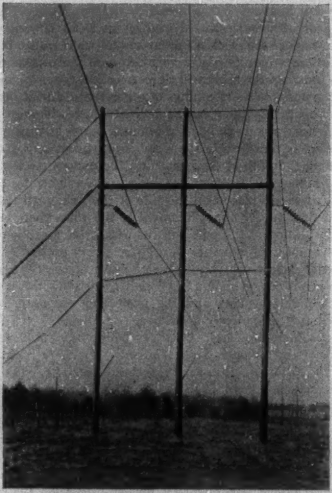

FIG. 12—132-KV ANGLE STRUCTURE WITH LIGHTNING DIVERTING CABLES GROUNDED BY A GUY

experience data from individual systems would merit separate treatment and it is regretted that only a composite summary could be presented in this paper.

## Discussion

**A. O. Austin:** At first glance it would appear that the performance of systems making use of wood may be more or less erratic. However, it would seem that this may materially be improved as we gain more information or apply a more careful analysis to the results of operation. More and more wood transmission lines are being installed in which the performance is practically 100 per cent. However, in these lines it will be found that there are certain fundamentals which must be given consideration. Work upon a reliability or performance index tends to show up the relative value of certain types of construction or the possible shortcomings of other types, and it is certain that if an operating index can be devised which will show up the various factors, wood can be used to much better advantage.

The effect of moisture in the wood is of utmost importance in determining the path of discharge and the damage to the wood. This has been clearly recognized by many as lightning rods or shunting wires are placed on the side of the pole until the poles have had time to dry out. Removal of the wires then develops the full insulation of the pole and the shattering may be negligible. The amount of moisture and the necessary protection to the wood varies considerably in different parts of the country and must be given consideration. At higher altitudes the moisture content generally is less and the protecting air path weaker, which reduces the tendency to shatter.

Where sufficiently high flashover voltage is obtained the resistance of the air path has a tendency to recover rapidly and prevent the follow-up of normal frequency currents. The use of the wood makes it possible to obtain exceedingly high flashover values as well as abnormally long discharge paths even for low voltage lines, the elimination of which should carefully be guarded against. This can best be accomplished by simple structures.

A direct hit to a transmission conductor certainly is going to cause a flashover if dependence is placed only upon the sizes of insulators commonly used. However, if the length of the arc could be made sufficiently long, the follow-up of normal frequency current can be prevented and the line will not be tripped out.

A high ground resistance or a high impedance in the transmission line or in the neutral will limit the current tending to follow an electrostatic discharge from a direct hit so that the normal frequency may be shut off. A high ground resistance is not necessarily a disadvantage in a wood pole line which makes use of the insulating value of the wood, but unfortunately a high ground resistance generally goes with a low ground capacitance so that the effective height and exposure of the transmission line is increased. However a high ground resistance or low ground capacitance generally is a serious limitation to ground wire protection, hence the use of ground wires which materially reduce the insulation of the wood may seriously increase the tripouts in some sections.

While wood is very valuable in increasing the effective arcing voltage between conductor and ground and in eliminating trouble from birds, it is subject to shattering and burning. The protecting gap can be used to prevent shattering but it is believed that improved methods of impregnation will make it possible to reduce the gap protection materially with the result that increased flashover voltage may be obtained. Multiple wood members rather than single members of large section may so reduce the hazard from shattering that it is possible to develop the full effective length of the cross arm without protection. The increased cost of this construction apparently is well warranted. The same applies to the use of wood cross arms on steel towers.

Burning may be prevented by the use of a bleeder resistance which will permit taking advantage o f the insulation provided by wood even in fog districts where the leakage and charging current of the insulator is high.

It would seem that operating records will go to show that a successful wood pole line may be built in several different ways, but the best operating systems generally will be simple in construction with the effective insulation of the wood developed to a maximum. The development of high flashover values and the limiting of normal frequency current will do much to prevent tripouts, as most disturbances originate with a single phase to ground.

Records such as those shown by Mr. Melvin are exceedingly valuable as they show the possible limitations with different types of construction.

**Edward Beck:** Mr. Melvin has described experience with drainage schemes involving arc interrupting devices. The text indicates that the devices mentioned in the paper resemble the deion flashover protector described by Torok in his paper (No. 31-9) presented in January, 1931.

The experience, described in the present paper, with the arc interrupting devices is as follows:

1. On a 60-mile line with drain points on each structure a total of four outages occurred in one year, three of which the author ascribes to the protectors themselves.
2. On a 45-mile line with drain points separated one-half mile, six outages have occurred in two-thirds of a lightning season, all of which are ascribed to the protectors.
3. On a 28-mile line the performance has been good. The author does not specially attribute either of the two outages which occurred in two and one-half years to the protectors.

Were the outages produced by the protector as a result of failure to clear the circuit after being discharged by lightning or did they originate tripouts themselves without lightning as the primary cause?

Considering (1) and (2) together, it appears that in a total of 10 outages, 9 are laid to the protectors. This might lead the casual reader to reserve judgment on the usefulness of this principle of protection. However, experience with the deion protector invented by Torok and developed by the Westinghouse Company has definitely proved that a relatively wide field for it exists and that in this field it is highly useful. In the first stages of the development of Torok's invention it became evident that the application of the device would not be as simple or as universal as the application of the well known lightning arrester. It became evident also that if design data were carefully established and the protectors constructed in accordance with it, they would find a wide application and that in their field they could be applied with assurance. This requires careful design, construction, and application based on system conditions. Deion flashover protectors have been manufactured for several years and as a result of the painstaking development work it is possible either to pronounce an application unsuitable or to apply them with confidence. Consequently the operating experience with these deion protectors has been good.

To illustrate the importance of careful application; in a certain installation of deion protectors some protector failures occurred. It was subsequently found that the currents to be interrupted were higher than those originally considered. Other installations of deion protectors have given satisfactory operating results. This is no doubt the result of careful development, design, construction and application.

The application of deion protectors was reduced to an engineering basis early in the development. It has been entirely feasible to decide that an application is suitable or unsuitable. If it is suitable the application of the device may be made with good results. Field experience with deion protectors substantiates this. If protector failures occur early in their life, they are attributable either to weakness in the design of construction or to misapplication.

**O. S. Hockaday:** While somewhat aside from the main theme of this paper, the following operating experience may be of interest:

Mr. Melvin points out that while the utilization of wood insulation in itself may not materially decrease line tripouts from lightning, there is some evidence to indicate that the dynamic follow current will be reduced.

On a Texas system of moderate capacity, 200 miles of 66-kv wood H-frame suspension type construction was put into operation late in 1927, no particular advantage being taken of the wood as insulation. During the following two years it was necessary to charge out an average of 60 insulator disks per year on account of burning from flashovers. In an effort to reduce lightning tripouts, the construction was then modified to utilize as much as possible the wood in the structures. Although lightning was about as severe during the two years which followed, the number of replacements dropped to an average of six. Burning of conductors was also reduced to some extent.

During the spring and summer, the transmission system just referred to is badly infested with ravens. These have been responsible in times past for a good many outages. On some lines tripouts from this cause were as frequent as those from lightning. On a particular 66-kv line of pin type construction, 61 miles in length, 42 tripouts occurred within a year which were attributed to these ravens. Gaps were installed in the pole ground wires in 1930 and since that time no tripouts whatsoever have occurred which were known to have been caused by the birds.

These instances substantiate Mr. Melvin's observation that utilization of the wood insulation has advantages other than those from the standpoint of lightning.

**H. L. Melvin:** In Mr. Austin's discussion he suggests the possibility of providing arcing distances of sufficient length to prevent the follow of dynamic current. Operating experience with high voltage lines of conventional construction, and even those employing long guy insulators as described in the paper, the tests made by Brookes, Southgate and Whitehead, also experience on lower voltage lines, do not indicate this type of design as a very practical method for attacking the lightning interruption problem. In the lower voltage ranges, such a design might be feasible but it has the serious objection of raising the lightning insulation strength of the lines to values considerably in excess of terminal equipment and apparatus. Furthermore, with such equipment installed at rather frequent intervals on the lower voltage lines, lightning flashover with dynamic follow-up still would be expected at these points.

The treatment of wood, no doubt, has considerable merit particularly if its life is extended, its mechanical strength under weather conditions improved, and if its lightning insulating strengths are increased and made more uniform. If the wood is exposed to frequent direct lightning discharges, it is the opinion of the author that it should be protected from damage whether treated or not.

Referring to Mr. Beck's discussion the arc interrupters, originally installed on the lines of the Arkansas Power & Light Company, were made up locally by Mr. Pittman from expulsion fuse tubes. Later a few deion tubes, as described in the paper by Mr. Torok were installed. The arc interrupters installed on the two additional lines also were of an experimental design using conventional expulsion fuse tubes. It might be added that the arc interrupter, deion flashover protector, and the expulsion protective gap, are all devices for interrupting the dynamic follow current.

Answering the questions raised regarding line performance, the tripouts which occurred on the lines employing the drainage scheme, were due to flashovers at structures not equipped with arc interrupters or to electrical and mechanical failures of the interrupters. As stated, the tube failures were not entirely unexpected as they were of an experimental design and their interrupting capacities as well as the methods of mounting had not been carefully worked out.

The manner in which wood has been used to minimize flashovers, as described by Mr. Hockaday, is of interest and very important. Good overall performance of lines should be the objective, and to accomplish this, the design must take into account all the elements adversely affecting operation, mechanically and electrically.

It is desired to emphasize that the lightning and short time 60-cycle insulation strength of wood can be utilized to advantage in practically all types of line construction and voltage classes. It is of particular value in combination with properly installed overhead ground wires or dynamic follow current interrupting devices, or for controlling arcing paths to minimize insulator damage. Very high insulation alone to lightning voltages, such as can be obtained through the use of long wood guy insulators and poles, has not proved effective for materially reducing lightning flashovers. The extensive application of this type of construction on the several transmission systems, largely in an experimental manner, has been a valuable supplement to other investigations. The experience has assisted materially in demonstrating that lightning discharges contacting conductors and structures must and can be coped with if line performance is to be substantially improved.

# Light Sensitive Process Control

BY J. V. ALFRIEND, JR.*
Non-member

IN order to keep certain electrochemical processes functioning within tolerable limits without suitable automatic control, it has been necessary, in some cases, to resort to close supervision by chemists who regularly sample the process liquors, determine their concentration and take what corrective measures are indicated. This work can be accomplished by a skilled laborer under the direction of the chemist if there is only one variable and if this variable is responsive to colormetric analysis either by the addition of an indicator or by its own color or opacity.

However, even this is expensive, slow, and inaccurate. The accuracy in the best of cases will vary with the health and fatigue of the analyst, with the conditions of illumination, and with the pressure of other work. Furthermore the analyst must change the speeds of pumps, conveyers, compressors, etc., and either hope that the correction is sufficient or waste valuable time waiting for the correction to take effect before he can obtain a check sample.

Recent developments in the matching of colors, the measurement of the intensity of smoke, and the automatic control of illumination indicated that colormetric process control might be obtained automatically by some modification of this new equipment which has proved commercially successful. Therefore a study was made covering the variables encountered in process control that should affect a light sensitive device similar to those just mentioned. The following list† gives a few applications where automatic control is definitely advantageous and where the variable chemical affects the shade or opacity of a liquor either directly, or indirectly by the addition of an indicator.

In metal flotation the maximum recovery is possible over a very narrow range of hydrogen ion concentration. The addition of an indicator to a filtered sample is required to bring out the definite shade corresponding to the concentration. Both the filtration and the addition of indicator can, of course, be made automatic. The lime feed can then be controlled for a definite hydrogen ion concentration at the launder or in the flotation tanks.

In electrolytic reduction plants, close control must be exercised over the acid concentration of fresh electrolyte from the leaching vats, and the spent electrolyte from the electrolytic tanks in conjunction with the flow of make up acid if required by the process. The acidity of the waste liquors should at least be indicated and preferably regulated. Determination of hydrogen ion concentration by colormetric methods and the control of pump speeds and electrolytic current flow will maintain the desired balance and give the necessary indications.

In electrolytic refining the best power efficiency is obtained at a definite hydrogen ion concentration, which is steadily reduced as the electrolyte increases in copper content. Control of this concentration by colormetric methods affecting the speeds of the circulation pumps and the current flow in the stripping tanks will maintain the desired acidity.

Numerous other applications in the electrochemical field will naturally occur to those interested in such processes. As a matter of interest a short list is given below of applications outside the field of electrochemistry but which bear upon this problem.

In the recovery of the sand used in the washing of coal it is necessary to keep the percentage of solid matter in the waste water between specified limits in order to obtain maximum recovery. The opacity of a thin stream of the effluent liquid is a definite criterion of the per cent solid matter contained.

In municipal water plants using chlorination it is necessary to regulate the amount of excess chlorine. The addition of an indicator to a sample of such water gives a color corresponding to the amount of excess chlorine present.

In paper mills the acidity of the paper stock solution and the concentration of the black liquor must be closely controlled. The acidity of the paper stock solution can readily be determined by the addition of an indicator to a sample and the opacity of the black liquor is a function of its concentration.

Two concentration regulator schemes have been worked out for applications in this class of service. The first or "balanced bridge" arrangement utilizes two light sensitive photo tubes simultaneously to inspect the light transmitted through a sample of the unknown liquor and the light transmitted through a standard colormetric sample representing the desired quantity of the variable chemical. The second or "null" method uses a single photo tube inspecting simultaneously the light transmitted by the unknown sample and the known sample. The "balanced bridge" arrangement utilizes established light sensitive circuits assembled in such a way as to perform the new function. It has the slight disadvantage of requiring recalibration from time to time because of the possibility of discrepancies in characteristics developing with age of the tubes. No such recalibration is necessary with the "null" method because, as the term implies, the regulation effects a zero response from the equipment when the percentage of the varying chemical is correct. The advantage of the "balanced bridge" arrangement is that it can also be used as an indicator whereas the "null" method does not permit its use as an indicator without the recalibration which it is designed to avoid as a regulator. Otherwise the two schemes are very similar in economy, speed and accuracy.

Fig. 1 shows a "balanced bridge" arrangement of photo tubes designed to regulate the hydrogen ion con-

centration of a flotation liquor, by controlling the speed of a conveyer which feeds lime to the process and maintaining this speed constant between corrective impulses received from the photo tubes. The schematic diagram is complete up to and including the motor drive for the lime conveyer. The mechanical equipment such as sampling, filtering, adding of indicator and placing before the photo tube are omitted because these features will change with individual applications. It should be noted here that only minor changes of the equipment shown in the diagram are required to make it applicable to the control of solenoid- or motor-operated valves or motor-operated rheostats and similar equipment encountered in regulating the flow of solids, liquids and gases.

The principle of operation is briefly as follows: Two photo cells are connected in a wheatstone bridge circuit which is supplied with direct current by a *B* eliminator. Potentiometer 1 constitutes one side of the bridge, and the two photo tubes the other side. The two photo tubes are illuminated from the same light source, not shown in the diagram. In front of one photo tube is placed a standard color sample in a glass tube, while the fluid to be controlled flows through a similar glass tube in front of the other photo tube. It is apparent that any variations in light intensity due to varying lamp voltage will not have any effect on the balanced bridge circuit. If the alkalinity of the fluid changes the bridge becomes unbalanced so that the voltage on the grid of tube No. 2 will differ from the grid voltage on tube No. 3. The result of this unbalance is that the grid of one of the grid glow tubes becomes more negative and the grid of the other tube becomes positive. Positive grid bias on the grid glow tube causes a breakdown of the tube so that for example relay III will become energized and close its contacts. It should be noted that tubes No. 2 and No. 3 are connected in a wheatstone bridge circuit which is normally balanced. For this reason, variations in supply voltage will not affect the calibration of this part of the equipment.

When relay III operates, relay V is closed and seals itself in, and voltage is applied to tube 4 which, in combination with relay II, acts as a time delay device. Depending upon the adjustment of potentiometer 6 a time delay up to one minute can be provided between the instant of closure of relay V and the instant of closure of relay II. Relay V in closing also operates the motor-operating relay VII, which causes the motor-operated rheostat to move and readjust the speed of the driving motor. Relay VII will remain closed until relay II is energized, since "break" contacts of relay II are connected in series with the coil or relay VII. During this period the motor speed is being readjusted.

When a correction has been made it is essential to prevent a second correction from being made until the effect of the first correction has been recorded by the photo tubes. For this reason a second time-delay relay is provided which may be adjusted for a time delay up to five minutes and which is so connected in the circuit that during this time interval no rheostat operation can take place. This second time-delay relay consists of relay I, tube No. 5 and associated equipment. It will be noted that the timing of this combination starts with the closure of relay II. When relay I operates, relay V

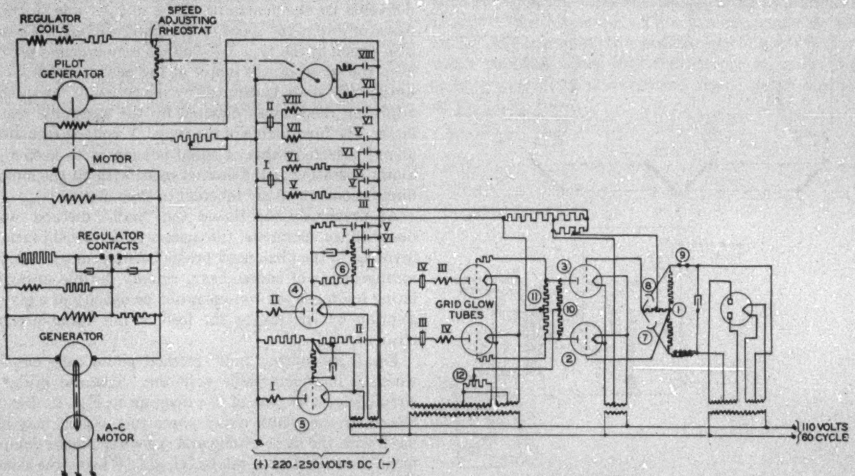

Fig. 1—Concentration Analysis Regulator Balanced Bridge Circuit

will be deenergized, and the equipment will be ready for the next adjustment.

Supposing the standard sample is arranged in front of photo tube 8, a recalibration of the equipment may be made either by changing the standard sample or by adjusting potentiometer 1. The instrument should be calibrated by opening switch 9, and connecting a high-resistance voltmeter across resister 10, by means of telephone jacks supplied for this purpose. Potentiometer 11 is then adjusted until the voltmeter reads zero.

The sensitivity of the regulator may be adjusted by means of potentiometer 12 which changes the constant negative grid bias which is applied to the grid glow tubes.

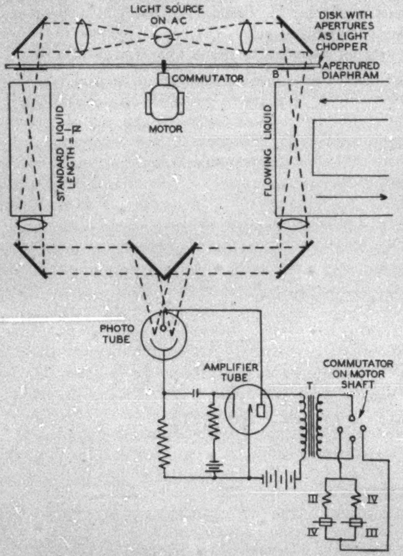

Fig. 2—Concentration Analysis Regulator Null Method

Proper operation of the electronic regulator described above is predicated upon the requirement that the motor operating the feed runs at the definite speed dictated by the regulator. These speeds must be maintained at the level indicated by the regulating equipment and not be permitted to vary from the dictated amount. Small motors do not possess flat speed torque characteristics particularly at varying armature voltages. Therefore, speed regulating equipment is added to the motor driving the feed.

The apparatus shown at the top of Fig. 1 outlines this speed-regulating equipment. The motor-generator set provides the armature voltage for the feed motor. This motor itself is to have coupled to it, a small pilot generator which will be excited from the 250-volt d-c supply. The voltage of the generator supplying the armature of the feed motor is regulated by a type UV voltage regulator. The coils of the regulator are connected across the armature of the pilot generator in series with a motor-operated speed-adjusting rheostat.

The functioning of this speed-regulating equipment in conjunction with the electronic equipment is as follows. Assume the regulating equipment to be in operation and the fluid being regulated to be of the proper color. Now assume that the color of the regulated liquid changes. As outlined in the preceding paragraph, this change will result in the operation of the motor controlled by relay VII or VIII. This motor is located on the speed-adjusting rheostat which modifies the current through the regulator coils connected across the pilot generator armature. The result of the movement of this rheostat is to change the calibration of the type UV voltage regulator which in turn modifies the voltage delivered by the generator of the m-g set and in turn raises or lowers the speed of the motor driving the feed. The action of the type UV voltage regulator is then to keep the speed of this motor at the newly chosen level until a new speed is dictated by the action of the speed-adjusting rheostat as directed by the electronic regulator. The functioning of the type UV voltage regulator at any selected value of speed is such as to keep the motor operating at the desired speed without the minor fluctuations which are inherent in such motors.

As previously mentioned the "null" method was designed to eliminate the necessity for recalibration involved in the "balanced bridge" arrangement. Both arrangements of course being equally flexible in regulating hydrogen ion concentration or opacity of a given solution by controlling the feed of the variable constituent.

Fig. 2 shows the "null" method photo tube circuit which is interchangeable with the "balanced bridge" circuit shown as part of the diagram in Fig. 1. For a colormetric regulator either photo tube circuit may be used, with the same timing and speed regulating equipment shown in Fig. 1, relays III and IV being the same in both figures.

Briefly the "null method regulating equipment" operates on the following principle: The lightbeams from a single light source are directed by a system of mirrors and lenses through two different paths onto a single photo tube in such a manner that one beam passes through a standard color sample and the other beam passes through the unknown liquid. An apertured diaphram is rotated in the path of the two beams so as to vary the cross section of the beams permitted to pass through the two liquids. The sum of the apertured areas *A* and *B* are always equal to unity, the aperture *A* varying from zero to 100 per cent while the aperture *B* varies from 100 per cent to zero.

Thus if the light transmitting qualities of the two liquids are identical the illumination of the photo tube will be unchanged as the diaphram is rotated, and therefore the output of the amplifier tube or its plate current will be constant direct current. With constant direct current impressed on the primary of transformer *T* there will be no output from the secondary, and relays III and IV will not be energized.

If the light transmitting quality of one of the liquids deviates a small amount from that of the other the illumination of the photo tube will vary as the diaphram is rotated and the plate current of the amplifier tube will therefore become a pulsating direct current. With pulsating direct current impressed on the primary of the transformer *T* the secondary will deliver only the alternating component, which in phase position and in magnitude will be proportional to the deviation in light transmitting qualities of the unknown fluid from that of the standard fluid. Since this alternating component is rectified by a mechanically driven commutator on the shaft of the motor which drives the diaphram, the direct current obtained will be proportional in sign and magnitude to this same deviation in light transmitting quality. With relay III set to pick up at a minimum value of positive current, and relay IV set to pick up at a minimum value of negative current, the speed adjusting rheostat and timing cycle explained under Fig. 1 will be set in operation just as these operations were started when relays III and IV of Fig 1 were energized by the breakdown of the grid glow tubes.

Since this circuit is a zero or "null method" and this feature is obtained by filtering out the direct component of the plate current of the amplifier tube, the regulator is insensitive to steady variations in applied voltage as affecting the circuit or the light source, and it is not affected by steady variations in temperature or changes in sensitivity of the tube itself within its working range.

## CONCLUSION

The concentration regulator schemes presented provide the accuracy, reliability and economy required of such devices. In addition they provide an adjustable amount of correction for each sample observed, together with an adjustable inoperative time, while awaiting the effects of one correction. Thus the equipment as designed may be applied to a wide variety of uses with the major problem being only the manner in which the unknown sample is prepared and placed before the eye of the photo tube.

# Skin Effect in Rectangular Conductors

## A Method of Measurement and Experimental Data

BY H. C. FORBES* and L. J. GORMAN*
Member, A.I.E.E. Member, A.I.E.E.

THE investigation covered by this paper was initiated, primarily, with a view to determining the skin effect at commercial frequencies in conductors of rectangular cross-section for cases where the return circuit is comparatively remote so that proximity effect need not be considered. These conditions are approximated in the case of bus bars of rectangular conductors in generating stations and substations where an isolated phase layout is employed. It was in connection with the design of such buses that the need for more complete information developed. In the process of obtaining the information desired, it was also possible to obtain basic data from which the skin effect in any non-magnetic rectangular conductor of ordinary dimensions can be readily determined for a wide range of frequencies. Accordingly, it was believed that the results obtained would be of general interest.

Considerable work, both of an experimental and theoretical nature, has previously been done on this subject, and particular mention is made of papers by H. B. Dwight,[1] and by A. E. Kennelly, F. A. Laws, and P. H. Pierce,[2] and of the accompanying discussion, particularly that contributed by Joseph Slepian, which have been published by the American Institute of Electrical Engineers.

It has been shown in these papers that the ratio of a-c to d-c resistance of a conductor may be determined as a function of the parameter, $P = \sqrt{\frac{8\pi f A}{\rho}}$, in which the symbols are defined as follows:

| | |
|---|---|
| $f$ | frequency in cycles per second |
| $A$ | area of cross-section in square centimeters |
| $\rho$ | specific resistivity in abohms per $\text{cm}^3$<br>(specific resistance in ohms is $\rho \times 10^{-9}$) |

This relationship suggested the possibility mentioned by Dwight of making tests at high frequencies on conductors of relatively small cross-section and applying the results to obtain the skin effect in large conductors at lower frequencies. This scheme of testing obviously offers great advantages because of the difficulties in making a-c measurements at the very low voltages which would be involved if large size conductors were tested at commercial frequencies. Accordingly, in this investigation the above principle was applied to tests on small rectangular conductors of various width-to-thickness ratios, tested at frequencies ranging from 22 to 287 kilocycles.

Two methods of measuring a-c resistance at high frequency were investigated; namely, the "substitution method" and the "resistance variation method," both of which are described in detail in the publications of the Bureau of Standards.[3] Essentially, each employs a test circuit, which includes the test specimen, coupled to a suitable source of high-frequency current, such as a vacuum-tube oscillator.

For the particular low-resistance circuits involved in this investigation, the "substitution method" seemed to give the most satisfactory results, and was best adapted to the use of the laboratory equipment on hand. In this method, it is not necessary to measure precisely the current or voltage, but only to provide a means of indication by which the emf may be controlled, and the test current adjusted and held at a convenient value for a particular test. Furthermore, it was found that the introduction into the test circuit of any of the high-frequency ammeters available added materially to the total resistance of the circuit, and thereby greatly decreased the sensitivity of the measurement. This proved to be a limitation in the use of the "resistance variation method." The use of an ammeter in the "substitution method" was avoided by the current-indicating device described below.

FIG. 1—OSCILLATOR AND EQUIPMENT FOR TEST CIRCUIT

Although the method of measurement is relatively simple, there are various precautions incidental to the use of high-frequency currents that must be observed in the practical application to avoid erroneous results. These precautions apply particularly to the shielding

and grounding of the various parts of the test equipment, and to the measurement and control of the high-frequency currents.

The oscillator and equipment used in the tests are shown in Fig. 1. A schematic circuit diagram is shown in Fig. 2. Essentially, the equipment consisted of a master oscillator coupled to a two-stage power amplifier, the second stage of which contained two 50-watt pliotron tubes. The primary of an air core transformer was connected to the output circuit of the amplifier. Special care was taken in the construction of the oscillator and in the selection of tubes and other equipment to insure a wave shape as free of harmonics as possible. With the oscillator operating at frequencies between 20 and 180 kilocycles, a test was made for harmonic frequencies up to 3,000 kilocycles. No harmonics of importance were found within this range of frequency. Precautions were taken to avoid possible errors due to "proximity effects," "end effects," and the influence of metallic structures located near the test circuit. These various influences and their effect on the measurements were checked in a series of preliminary tests.

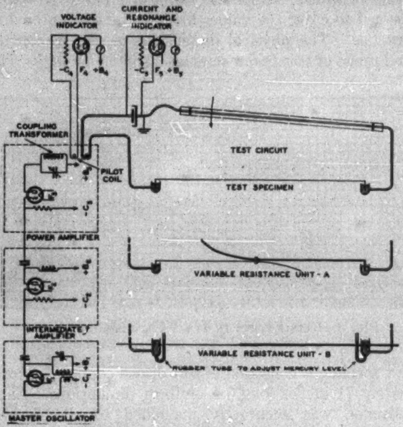

FIG. 2—SCHEMATIC DIAGRAM OF OSCILLATOR AND TEST CIRCUIT FOR SKIN EFFECT MEASUREMENTS

The test circuit shown in Fig. 2 comprises a loop containing the test specimen, a low-loss tuning condenser, and a length of heavy Litzendraht cable, required to complete the circuit. The oscillator coupling was made through a single turn of cable loosely coupled to the transformer primary. The condensers in the test circuit were selected with reference to the size of the loop, so that the circuit was approximately in resonance at the desired test frequencies. Adjustment for resonance was made by moving in or out the arm on one side of the loop, as indicated by the arrow in Fig. 2, thereby varying the size and inductance of the loop. This arrangement permitted a very fine adjustment of resonance, avoided the use of tuning coils, gave a test circuit of minimum resistance, and permitted the desired sensitivity in the measurements.

The emf induced in the test circuit was determined by means of the voltage indicator shown in Fig. 2. This consisted of a pilot coil closely coupled to the secondary turn and connected to the grid circuit of a vacuum tube, as shown. The indications on the milliammeter in the plate circuit of the vacuum tube were proportional to the emf induced in the pilot coil, and, since the same flux was interlinked with the secondary turn, the readings were proportional to the emf induced in this turn. By means of the indicator, it was thus possible to maintain a constant resultant flux interlinked with the secondary turn, and, therefore, a constant emf in the test circuit, by adjusting the plate voltage on the amplifier.

It was apparent that the resistance of the test circuit would have an important influence on the sensitivity of the measurement. The resistance of the circuit, not including the test specimen, was, therefore, kept as low as possible so that the resistance of the test specimen would constitute a large portion of the total circuit resistance. It was found that inserting an ammeter into the test circuit added appreciably to its resistance. Since in the method of measurement it is not essential to know the test current in amperes, the use of an ammeter was avoided by using a vacuum-tube indicator, the grid circuit of which was connected across the fixed condenser in the test circuit, as shown in Fig. 2. Since at any given frequency the drop across the condenser would be proportional to the current, this gave a means of indicating the point of resonance and served as a basis for making the adjustment of the variable resistance required to give a current equal to that obtained when the test specimen was in circuit. This arrangement proved quite satisfactory. An approximate calibration of the indicator was made by connecting a low-resistance, high-frequency ammeter in the circuit, and plotting readings on the indicator against ammeter readings at each of the various test frequencies. During the actual measurements, however, the ammeter was removed.

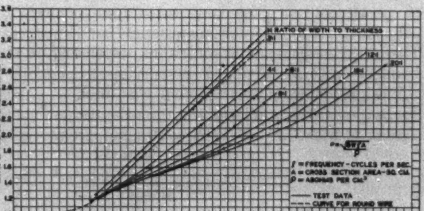

FIG. 3—SKIN EFFECT IN STRAP COPPER CONDUCTORS

The selection of a suitable resistance unit for use as a reference standard was an important factor in these measurements. The principal requirements were that the resistance be continuously variable, easily adjusted, and its construction such that when substituted for the test specimen it would not materially change the constants or configuration of the test circuit. These requirements were met by the round wire resistance units shown in Fig. 2 (*A* and *B*). Each type of unit was constructed of two sizes of copper wire, one somewhat larger, and the other somewhat smaller in cross-section than the test specimens. The type shown at *A*, Fig. 2, was provided with a slider by which the relative lengths of large and small wire could be easily adjusted. The second type consisted of two sizes of copper wire joined together, and placed in mercury cups so that sliding the unit either way varied the relative length of the large and small wire. The a-c resistance of straight round wire can be readily calculated from published formula.[3] The a-c resistances of the adjustable resistor units were therefore obtained by calculating the resistance of separate lengths of large and small wires measured between the contacts. This result was checked by reference to straight round wire specimens of uniform cross-sectional area, the a-c resistances of which were calculated. The accuracy of the method was found to be approximately one per cent.

Mercury cups were provided by which the test bars and the adjustable resistance unit could be easily interchanged. The resistances of the other connections were made as low as possible by the use of tinfoil between the contacts. The contact resistance, including that of the mercury cups, was approximately one per cent of the total resistance of the circuit. The resistance of the Litzendraht cable constituted approximately 58 per cent of the total circuit, and the test bar 41 per cent. These percentages varied somewhat, depending on the frequency and the particular test specimens in circuit.

The procedure of measurement was, first, to adjust the output of the oscillator and tune the test circuit to resonance with the test specimen in the circuit. The adjustable resistance was then substituted for the test specimen, and, with the output of the oscillator held constant, the resistance was varied until the same conditions of resonance were obtained in the test circuit. Since all other constants of the circuit were the same, the resistance of the variable standard unit was then equal to that of the test specimen, and its value was calculated from the relative lengths of large and small wires, as explained above.

The tests were made on specimens representing a range of width-to-thickness ratios of 1:1 to 20:1, which seemed to cover the values likely to be encountered in practise. The physical dimensions of the specimens, and range of test frequencies are listed in Table I. The test specimens consisted of soft drawn copper, approximately 71 inches long, of uniform dimensions. Each specimen was accurately machined to the desired width-to-thickness ratio, and precautions taken to insure sharp square edges. The d-c resistance was obtained by the usual bridge method, special care being given to securing specimens of uniform resistivity. Test specimens having different cross-sectional areas, but the same ratio of width to thickness, were selected so that experimental checks of the theory could be obtained by making measurements at different frequencies to satisfy the conditions of the parameter.

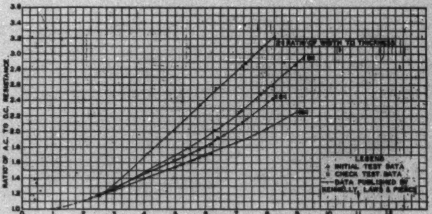

FIG. 4—SKIN EFFECT IN STRAP COPPER CONDUCTORS

The data obtained from the tests are given in graphical form in Fig. 3, in which the ratios of a-c to d-c

TABLE I—DIMENSIONS OF TEST BARS AND RANGE OF FREQUENCIES USED IN MEASUREMENT OF A-C TO D-C RESISTANCE RATIOS

| Test bar number | Average dimension inches a | b | Average area square inches | Actual ratio a/b | Nominal ratio a/b | Length inches | Test frequency range Kilocycles |
|---|---|---|---|---|---|---|---|

| 2A | 0.0805 | 0.0404 | 0.00325 | 1.99 | 2 | 71 | 22 to 179 |
| 3A | 0.1205 | 0.0300 | 0.00362 | 4.02 | 4 | 71 | 22 to 179 |
| 4A | 0.1491 | 0.0256 | 0.00382 | 5.83 | 6 | 71 | 22 to 232 |
| 5A | 0.1600 | 0.0202 | 0.00323 | 7.93 | 8 | 71 | 22 to 232 |
| 1B | 0.1399 | 0.0718 | 0.01004 | 1.95 | 2 | 71 | 26 to 75 |
| 2B | 0.2706 | 0.0454 | 0.01228 | 5.96 | 6 | 71 | 26 to 75 |
| 3B | 0.2812 | 0.0357 | 0.01002 | 7.88 | 8 | 71 | 26 to 75 |
| 1C | 0.242 | 0.021 | 0.00508 | 11.72 | 12 | 71 | 45 to 287 |
| 2C | 0.322 | 0.021 | 0.00676 | 15.31 | 16 | 71 | 45 to 179 |
| 3C | 0.403 | 0.021 | 0.00846 | 18.18 | 20 | 71 | 45 to 179 |

resistance are plotted as a function of the parameter. The curves in Fig. 4 show a comparison between the data obtained in these tests and those published by Kennelly, Laws, and Pierce for width-to-thickness ratios of 8 and 16. The curves also show the agreement obtained between tests on specimens of the same width-to-thickness ratios, but of different cross-sectional areas. A very close agreement was obtained with the published data and between specimens of different sizes. It is felt that the consistent results thus obtained speak well for the reliability of the data.

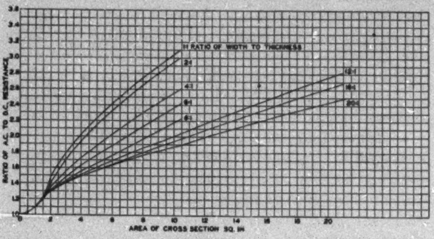

FIG. 5—SKIN EFFECT IN STRAP COPPER CONDUCTORS AT 60 CYCLES

From an inspection of the data given in the paper by H. B. Dwight (see reference 1), it might have been anticipated that, except for the initial curvature near the origin, these curves would be straight lines. Apparently, however, this is by no means the case, although it is approximately true within the limits of the tests in the particular instance of the conductors having width-to-thickness ratios of 1:1 and 2:1. For other width-to-thickness ratios, the curves tend to bend upward for values of parameter above 5.5. The close agreement between the curve for a round wire and the curve for the 2:1 specimen is interesting to note, and also the fact that the skin effect in a square conductor is consistently greater than that of a round wire.

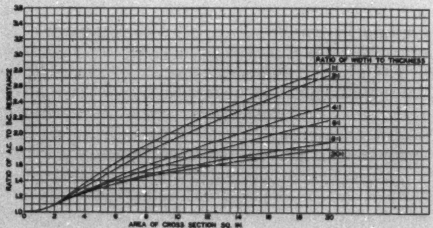

FIG. 6—SKIN EFFECT IN STRAP COPPER CONDUCTORS AT 25 CYCLES

In order to reduce the data to convenient form for determining skin effect at commercial frequencies, Figs. 5 and 6 were prepared. From these curves, the skin effect in rectangular conductors at 60 cycles or 25 cycles can be readily determined. Similar curves for any frequency can be easily calculated from the basic data given in Fig. 3.

## Discussion

**J. E. Clem:** The authors state that the ratio of alternating-current resistance to the direct-current resistance of a conductor may be expressed as a function of the parameter $P = \sqrt{\frac{8\pi f A}{\rho}}$. This statement, while perfectly true, without further qualification, might lead to a misunderstanding, since apparently it indicates that the eddy-current loss might vary as the square root of the frequency.

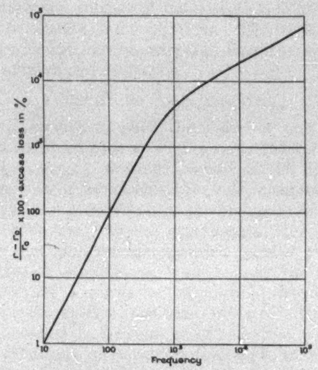

FIG. 1

If the extra loss be segregated it can be shown that the extra loss varies with the square of the frequency in the neighborhood of 60 cycles and that for very high frequencies this extra loss varies as the square root of the frequency. This is illustrated in Fig. 1. Since this is the case it is essential that extreme caution be used in applying the results of tests made at high frequencies or extreme conductor proportions to determine the excess loss at commercial frequencies.

There is a tendency among some writers to consider skin effect, proximity effect, eddy-current loss, and unequal distribution of current as separate phenomena. There is no justification for this, since they are all produced by the magnetic flux passing through the conductor. Several years ago, I developed a method of calculating the eddy-current loss in transformer conductors. Fig. 1 was calculated using this method. These same equations have been used to calculate the extra loss due to unequal division of current in parallel conductors and when properly applied give the same losses as formulas developed to calculate the supposed entities, skin effect, and proximity effect.

**H. C. Forbes and L. J. Gorman:** The authors wish to point out that while their paper states that the ratio of alternating current to direct current resistance may be determined as a function of the parameter $P$, which is defined in the paper, it makes no statement whatever in regard to the determination of eddy current loss which under the conditions of the tests is believed to have been wholly negligible. In the same way as is pointed out in the paper it was the intent to keep the return circuit for the current remote so that the proximity effect also would be negligible. It is believed accordingly that the increase in resistance as compared to the d-c resistance as obtained by the tests is all due substantially to the non-uniformity of distribution of current in the conductor resulting from the phenomenon commonly termed skin effect.

It seems to the authors that Mr. Clem's suggestion that there is no justification for separate consideration of skin effect, proximity effect, and eddy current leads to hopeless confusion in the analysis of such losses.

# A Standard of Low Power Factor

W. B. KOUWENHOVEN* and LEO J. BERBERICH†

## INTRODUCTION

IN the study of the electrical characteristics of insulation, an accurate knowledge of the power factor and loss is of importance. The measurement of these factors is affected by many variables and unsuspected errors are often present in the results. A survey of the literature on the subject of dielectric loss measurement reveals clearly the lack of a reliable reference standard.

The need for a standard load which should simulate the power factors found in cable samples as well as in insulating oils has long been recognized. From time to time a number of schemes and devices has been suggested for verifying the accuracy of the loss measuring equipment. Some of these depend upon the check obtained by the measurement of the increase in loss produced by connecting a resistance in series[1,2,3] with the sample under test. The introduction into the circuit of a series resistance, aside from the fact that it may have an appreciable phase angle, disturbs the potential distribution and leaves much to be desired from the standpoint of accuracy. Another scheme is to measure two or more specimens singly and then in parallel. The accuracy of this check is open to question because of the many variables such as temperature and voltage that affect the dielectric loss of a given specimen.

Attempts have been made at various times to construct suitable standards of glass or similar materials with the hope of obtaining a satisfactory load. Of these, the ones developed by the Electrical Testing Laboratories of New York[3,4] are by far the best. Their power factor, however, cannot be computed but has to be measured in the very circuit which itself is subject to error. It is clearly analogous to the efforts of a man to lift himself by his own bootstraps.

All of the above methods for checking dielectric loss measuring equipment are qualitative in their nature and none of them can be considered as a basic standard. In addition, their correctness rests upon the very equipment whose accuracy they are supposed to verify.

A new standard of low power factor has recently been developed in the Electrical Laboratories of The Johns Hopkins University which it is hoped will meet the needs of workers in the field of insulation. It consists essentially of a loss-free shielded and guarded compressed air capacitor connected in series with an ideally shielded resistor. It is the purpose of this paper to present a description of the new standard as well as some data concerning its performance in checking Schering bridges. The standard may, however, be used for verifying the accuracy of other types of low loss measuring apparatus.

Since a dielectric specimen can be most easily and satisfactorily represented by the combination of a capacitance and a series resistance, these were chosen to form the basic elements of the standard. In order that this circuit possess characteristics desirable in such a standard load, the capacitance should be loss-free and properly shielded, the resistance should be essentially pure and its introduction into the circuit should not disturb the equality of the potentials of the guard and main circuits of the capacitor. The power factor of such a circuit can be computed from the values of its capacitance and resistance.

## COMPRESSED AIR CAPACITOR

It was decided to build the capacitor unit of the low-loss standard with a capacitance of 500 $\mu\mu$f; which could be operated without corona at 25 kilovolts effective. In order to reduce its bulk, compressed air at a maximum pressure of ten atmospheres was chosen as the dielectric. Earlier experiments have demonstrated that shielded and guarded parallel plate air capacitors at atmospheric pressure and low relative humidity are loss-free at commercial frequencies.[5] Careful tests, which will be described later, proved that the compressed air dielectric is also loss-free.

The cylindrical air capacitor developed for this work is shown in Fig. 1. The area of the guard electrodes equals very nearly that of the main electrode thus giving approximately a one to one ratio between the guard and main capacitances. The flared shields at the extreme ends are connected to ground. These eliminate the possibility of any leakage current from the high-voltage electrode reaching either the guard or measuring electrodes. They also serve to increase the electric strength of the capacitor. Fig. 1 shows that the guard electrode is extended in the form of a shield so as to cover completely the back of the main electrode, and that the lead from the main electrode is shielded by the continuation of the guard in the form of a tube.

The air capacitor as constructed consists of three coaxial brass tubes, the middle one acting as the high voltage electrode. This is 23 in. (58.5 cm) in length, 8 in. (20.32 cm) outside diameter, and 1/8 in. (0.32 cm) thick. There are two low-voltage tubes, one inside and the other outside of the high-voltage electrode. Each low-voltage tube consists of five sections. The central section, 9 in. (22.86 cm) in length, forms the measuring electrode. This is protected by two guard ring sections,

*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

one above and the other below, and two bell-shaped grounded shields, one at each end of the assembly. Each guard section is 4½ in. (11.43 cm) in length. Each section of both low voltage tubes is separated from the adjoining section by a gap of 1/16 in. (1.6 mm) maintained by the use of bakelite rings. Each bell-shaped shield has an axial length of 2 in. (5.08 cm), making the overall length of the complete low voltage tube 22¼ in. (56.5 cm). The assembly of the inner low-voltage electrode is shown in Fig. 2.

The spacing between the high- and low-voltage electrodes is fixed at 0.2 in. (5.08 mm) by means of grooves cut in bakelite disks between which the tubes are clamped. In Fig. 2 the lower disk may be seen in place. The high- and low-voltage electrodes are clamped together between the upper and lower bakelite spacing disks by means of four one-half-inch brass rods. The assembly is mounted on a twelve-inch blind pipe flange as is shown in Fig. 1. This figure also shows the complete shielding of the main electrode and its lead.

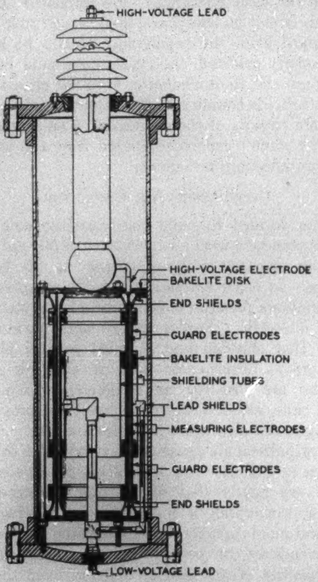

FIG. 1—SECTIONAL VIEW OF THE COMPRESSED AIR CAPACITOR

The capacitor is enclosed in a standard twelve-inch wrought iron pipe 4 ft (1.2 m) in length. This has ample strength to withstand the pressure used. The high-voltage bushing is a 50,000-volt circuit-breaker bushing furnished by the Locke Insulator Company. Care was taken to eliminate all sources of corona inside of the capacitor, all edges were rounded or protected.

The use of compressed air in capacitors is not new. Fessenden[6] and Max Wien[7] were among the pioneers in its use. With the introduction of guard ring capacitors further developments and improvements were made by Schering[8] and others. Palm[9] found that the dielectric strength of air increased almost directly as the pressure, for pressures up to ten atmospheres. There is a slight change in the dielectric constant $\epsilon$ with pressure. Its variation is given by the expression[10]

$$\epsilon = \frac{1 + 2\,c_1 d_1}{1 - c_1 d_1}$$

where $c_1$ = constant = $195 \times 10^{-6}$

and $$d_1 = \frac{P}{1 + 0.003665\,T}$$

where $P$ = pressure in atmospheres for the range 0 to 175 atmospheres

and $T$ = temperature for the range 0 to 70 deg C.

The variation in dielectric constant for a pressure change from atmospheric to ten atmospheres amounts to less than one-half of one per cent. Consequently, the effects on the capacitance of the standard of any pressure changes due to air leakage are negligible.

## TESTS OF THE CAPACITOR

After assembly the capacitance of the air capacitor was measured by two entirely different methods. The capacitance of the main plate was found to be 517.5 μμf and that of the guard 530 μμf. This is sufficiently close to a one-to-one ratio for our purpose and the ideally shielded resistors were adjusted in accordance with these values as will be explained later.

At an air pressure of ten atmospheres the capacitor withstood 30 kilovolts continuously without any indication of corona. When the voltage was raised to 35 kilovolts a flashover occurred across the surface of the bakelite spacing disk between one end-shield and the high-voltage tube. The damaged bakelite spacing disk was repaired and a second test, made at 30 kilovolts, also gave no evidence of corona or other trouble. It is, therefore, clear that the capacitor can safely withstand its working potential of 25 kilovolts.

Experiments conducted both here[5] and abroad[11] have demonstrated that at atmospheric pressure and low relative humidity, an adequately shielded air capacitor is loss-free as far as measurements on commercial insulation are concerned. The compressed air capacitor was, therefore, compared with shielded flat-plate capacitors of this type. The tests were made at 60 cycles in two Schering bridges, one having a maximum voltage range of 1,000 volts and the other of 10,000 volts. Each of these bridges is completely shielded and guarded and has a power factor sensitivity of ± $5 \times 10^{-6}$. The compressed air capacitor was inserted in place of the specimen in each bridge in turn and its power factor determined at temperatures ranging from 10 deg to 27 deg C, and pressures from atmospheric to 175 lb gage, care being taken to remove the moisture from the compressed air. In every case the power factor of the compressed air capacitor was found to be zero to within the accuracy of the bridges. We, therefore, concluded that an adequately shielded and guarded compressed gas capacitor is loss-free and that it acts as a pure capacitance. Its capacitance is independent of voltage and temperature variations and its characteristics are those of a standard.

Fig. 2—Inner Low-Voltage Tube of the Capacitor

## Series Resistors

The power factor of a load consisting of a capacitance and a series resistance may be accurately computed provided their values are known and that they are free from defects. Tests proved that the compressed air capacitor could be considered as a pure capacitance. The problem of constructing the second element of the combination, namely, a pure resistance for alternating current work, was more difficult.

A resistor in addition to its ohmic resistance possesses three parasitic properties, self-inductance, self-capacitance and earth-capacitance. The first and second may be made small by the use of the proper winding. The third is the most troublesome and its elimination is a difficult problem.

The capacitance to earth of a resistor varies with the position of the coil with respect to surrounding objects. The simplest way of fixing its value is to enclose the unit in a metal container maintained at a definite potential with respect to the voltage drop across the coil.

In a shielded and guarded capacitor of the type constructed it is of prime importance that exact equality of potential be maintained between the guard and main electrodes and their leads. Otherwise, there will be a transfer of energy through the capacitance existing between these two circuits which will cause errors in the results, as pointed out by Kouwenhoven and Baños.[12]

Fig. 3A shows a shielded resistor in which the shield is maintained at a potential equal to that of the mid point of the working resistance $R_W$ by means of a tap from the guard resistance $R_G$. This connection to some extent balances earth capacitance effects of the resistance $R_W$, the equation being given in the appendix. At the same time, by use of the proper value of guard resistance, $R_G$, the equality of potentials between the guard and main electrodes is maintained.

A better arrangement is obtained by subdividing the resistance into sections, shielding each section separately and maintaining each shield at its proper potential. Shielded resistances of this type have been described by Orlich,[13] Kouwenhoven,[14] Hiecke,[15] Silsbee[16] and others.

If we carry subdivision of the resistor to the limit where each element of the working resistance $R_W$ is shielded by a corresponding element $R_G$ in the guard circuit, we have the best arrangement and what may be called an "ideally" shielded resistor. Fig. 3B illustrates schematically such a resistor. The guard resistance is coaxial with and completely surrounds the working resistance. Both the guard and working resistances are uniformly distributed and their values chosen so as to maintain equal potential drops along their lengths. Under these conditions there is no voltage across the capacitance between the two resistances because the potential is the same at all corresponding points along the two circuits. Therefore, with this method of shielding, earth capacitance effects are reduced to a minimum. This type of resistance was chosen as the second element of the standard of low power factor and three units, one of 1,000 ohms, one of 5,000 ohms, and one of 10,000 ohms nominal values, were constructed.

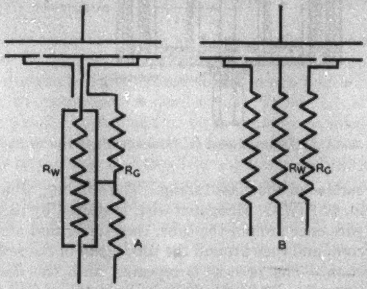

Fig. 3

A—Simple Type of Shielding

B—Ideal Type of Shielding

A theoretical discussion of the simple shielded resistor and of the ideally shielded resistor, Fig. 3 (A and B), is given in the appendix.

### IDEALLY SHIELDED RESISTOR

The working resistance, $R_W$, is wound on a one-inch outside diameter pyrex glass tube in accordance with a method developed by Dr. Frank Wenner of the Bureau of Standards. A heavy cord is placed axially along the surface of the glass tubing. The winding, which is of No. 40 A.W.G. Manganin wire, is started by passing the wire once around the tube, then under and around the cord, and then around the tube again in the reverse direction. The process is repeated until the desired resistance is obtained. Every alternate turn of this type of winding is reversed, thus reducing its self-inductance and self-capacitance to a minimum.

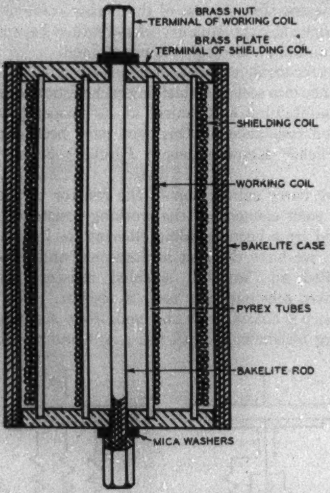

FIG. 4—A 5,000-OHM IDEALLY SHIELDED RESISTOR IN SECTION

The guard resistance, $R_G$, is wound on a two-inch diameter pyrex tube. This winding has the same axial length as that of the working circuit. It consists of a double layer winding with the layers wound in opposite directions and connected in parallel after annealing and adjusting.

A sectional view of the 5,000-ohm ideally shielded resistor is given in Fig. 4. The tubes carrying the working and guard windings are mounted coaxially between brass plates. The resistors are enclosed by bakelite panels fastened to the brass plates. Convenient terminals are provided for connecting any one of them in series with the capacitor. Fig. 5 is from a photograph of the three ideally shielded resistors constructed for the low-loss standard. The values of the resistances of the circuits of the three ideally shielded resistors are given in Table II.

### TESTS OF THE IDEALLY SHIELDED RESISTORS

The phase angles of the ideally shielded resistors were measured in a special alternating-current bridge developed for the purpose. This bridge and the method of measurement is described elsewhere.[17] The resistors were tested at both 60 and 500 cycles and their effective inductance was measured with a fixed value of current, $I_W$, flowing through the working resistance while the current $I_G$ through the guard circuit was varied. The effective inductance[18] of a resistance is given approximately by the expression $L-CR^2$, where $L$ is the inductance, $C$ the capacitance and $R$ the resistance of the unit.

The results of the tests are given by the curves of Fig. 6. From the curves it is evident that the effective inductance of the resistors is negative when the guard circuit is carrying less current than the working circuit. However, when the guard current becomes greater than the working current the effective inductance becomes positive. This phase change is caused by the reversal of the capacitance currents between the two circuits.

FIG. 5—THE THREE IDEALLY SHIELDED RESISTORS

In computing the phase angles of the resistors the average effective inductance as measured at 500 and 60 cycles was used. In Table I the phase angles of the resistances at 60 cycles are given for the condition of equal potential drops along both working and guard resistances.

TABLE I

| Resistor ohms | Effective inductance mh | Phase angle $\theta$—sec | Tan $\theta$ radians |
|---|---|---|---|
| 10,000 | −0.06 | −0.47 | −0.0000022 |
| 5,000 | −0.02 | −0.31 | −0.0000015 |
| 1,000 | +0.005 | +0.39 | +0.0000019 |

The phase angle of each resistor is less than $10^{-5}$ radians. This is considerably larger than that found by calculation from the equations given in the appendix. This discrepancy can be explained by the fact that in the measurement all parasitic effects are taken into account, whereas in the mathematical analysis earth capacitance only is considered and no account taken of the self-inductance and self-capacitance. The equations given in the appendix show that the effect of earth capacitance in the ideally shielded resistors is reduced to the order of $10^{-15}$ radians. In the simple shielding scheme Fig. 3A, the effect of earth capacitance is much larger, being, roughly, $5 \times 10^{-6}$ radians.

The small phase angles of the ideally shielded resistors may be neglected and they may be regarded as pure resistances in even the most precise dielectric loss measurements of today.

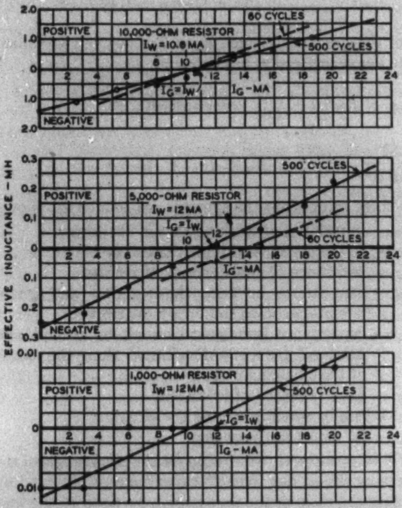

Fig. 6—Variation of Effective Inductance with the Variation of Current Through Shielding Coil

## The Standard of Low Power Factor

The combination of the shielded and guarded capacitor and an ideally shielded series resistor, therefore, forms a standard whose power factor can be computed accurately. The calculated values of the power factor of the standard at 60 cycles and the values of the resistances for equality of potential between main and guard electrodes of the capacitor are given in Table II.

TABLE II

| Resistor nominal value ohms | Working resistance $R_W$, ohms | Guard resistance $R_G$ ohms | Power factor of standard 60 cycles |
|---|---|---|---|
| 1,000 | 1,020 | 1,000 | 0.000195 |
| 5,000 | 5,106 | 5,000 | 0.000996 |
| 10,000 | 10,214 | 10,000 | 0.001993 |

## Checking of Schering Bridge

After the completion of the preliminary tests of the air capacitor and the resistors, the standard of low power factor was used to check the three Schering bridges in use in the Electrical Laboratories of The Johns Hopkins University. The results of tests on two of the bridges are given in Table III.

TABLE III

| Bridge | Voltage | Temp. | Gage pres. | P. F. |
|---|---|---|---|---|
| 1,000-Ohm Resistor | | | | |
| 1 | 1,000 | 22.9°C | 0 | 0.000196 |
| 2 | 3,000 | 21.2°C | 0 | 0.000194 |
| 2 | 5,000 | 22.8°C | 120 | 0.000196 |
| 2 | 10,000 | 22.5°C | 120 | 0.000193 |
| | | | Average | 0.000195 |
| 5,106-Ohm Resistor | | | | |
| 1 | 1,000 | 24.0°C | 105 | 0.000992 |
| 2 | 5,000 | 23.0°C | 107 | 0.000996 |
| 2 | 10,000 | 23.0°C | 107 | 0.000992 |
| 2 | 10,000 | 22.8°C | 100 | 0.000998 |
| 2 | 5,000 | 21.6°C | 175 | 0.001002 |
| 2 | 5,000 | 10.0°C | 100 | 0.000995 |
| | | | Average | 0.000996 |
| 10,214-Ohm Resistor | | | | |
| 1 | 1,000 | 24.0°C | 105 | 0.001983 |
| 2 | 5,000 | 23.0°C | 107 | 0.001993 |
| 2 | 10,000 | 23.0°C | 107 | 0.001997 |
| 2 | 5,000 | 22.8°C | 100 | 0.001990 |
| 2 | 10,000 | 22.8°C | 100 | 0.001986 |
| 2 | 5,000 | 10.0°C | 100 | 0.001997 |
| | | | Average | 0.001991 |

These tests were made at all three values of power factor of the standard. The average values of power factor given in Table III are almost in exact agreement with the computed values listed in Table II. In no case was a bridge found to be in error by as much as one per cent. It might well be mentioned here that it is quite remarkable that two Schering bridges which were built several years apart and which were of radically different arrangements should agree so closely.

The third bridge which was tested at 20 kv was found to be in error by a considerable amount. This bridge was carefully examined and cleaned. The principal source of error was discovered in an entirely unsuspected capacitance which was shunting one of its arms. Another source of trouble was found to be a capacitor whose calibration was in error. These defects were remedied and the calibration of the bridge for the range of the standard was then found to be correct.

## Conclusions

1. The standard of low power developed, consisting of a shielded and guarded capacitor and an ideally shielded resistor, represents satisfactorily a dielectric specimen.

2. Its capacitance is loss-free, and independent of variations in voltage, temperature and frequency.

3. Its resistance has a negligible phase angle and for practical purposes may be considered as a pure resistance.

4. Its values of capacitance and resistance may be determined accurately by independent measurements.
5. Its power factor and loss may be computed exactly.
6. Its value of power factor is independent of variations in applied voltage and temperature.
7. It possesses the primary requisite of a standard, namely permanence.

### ACKNOWLEDGMENT

The authors wish to take this opportunity to express their appreciation and thanks to Doctor F. B. Silsbee and Doctor F. K. Harris, both of the Bureau of Standards, for their assistance in this work.

## Appendix

### THEORETICAL RELATIONS

*Ideal Shielding.* In order to determine the effectiveness of the ideal method of shielding, the equivalent circuit of such a resistor was analyzed mathematically.

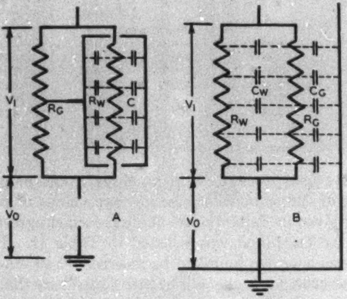

FIG. 7

A—EARTH CAPACITANCE SIMPLE SHIELD
B—EARTH CAPACITANCE IDEAL SHIELD

In this treatment the self-inductance and self-capacitance of the two coils were neglected. The distributed capacitance between the two coils and the distributed capacitance to earth of the shielding coil only were considered. The diagram of the equivalent circuit with the distributed capacitances indicated is given in Fig. 7B. The general case was treated where one end is at a fixed potential $V_0$ above ground and the other end at another fixed potential $(V_0 + V_1)$ above ground. This circuit is a special case of a transmission line or cable with uniformly distributed constants and thus Maxwell's equations apply.

In this treatment we are interested in finding an expression for the impedance of the working circuit. Since the derivation of the latter is rather lengthy and space limitations prohibit including it here, the final result only is given.

For the general mode of attack the reader is referred to Silsbee's[16] work, which treats a special case where one end of the resistance is grounded or $V_0 = 0$. The rigorous expression for the impedance involves a number of hyperbolic functions. Simplification was effected by expanding them into a rapidly converging power series which is easily analyzed. The first three terms of this series are:

$$Z_w = R_w \Bigg[ 1 - \left( \frac{7}{360} + \frac{15}{360} \frac{V_0}{V_1} \right) \omega^2 C_w C_G R_w R_G$$

$$+ j \left( \frac{31}{15{,}120} + \frac{63}{15{,}120} \frac{V_0}{V_1} \right) \omega^3 C_G C_W R_G R_W$$

$$(C_G R_G + C_W R_W + C_W R_G) + \ \ldots \Bigg]$$

For the special case when $V_0 = 0$ or one end grounded, the above expression becomes,

$$Z_{0W} = R_W \Bigg[ 1 - \frac{7}{360}\, \omega^2 C_W C_G R_W R_G +$$

$$\frac{31}{15{,}120}\, j \omega^3 C_G C_W R_G R_W (C_G R_G + C_W R_W + C_W R_G) + \ldots \Bigg]$$

In these expressions the symbols are defined as follows:

$Z_W$ = impedance of working circuit of resistor
$R_W$ = resistance of working circuit of resistor
$R_G$ = resistance of guard circuit of resistor
$C_W$ = capacitance between the working and guard circuits assumed uniformly distributed
$C_G$ = capacitance from guard circuit to ground also assumed uniformly distributed along the length of the shielding coil
$V_0$ = fixed potential of lower end
$V_1$ = rise in potential across the circuit
$\omega$ = $2\pi$ times the frequency

The approximate expression for the phase angle of the working circuit due to earth capacitance is obtained by taking the ratio of the first imaginary term to the first real term in the above series. Thus, for the special case of $V_0 = 0$, the phase angle at 60 cycles of the working circuit is,

$$\tan \theta_W \cong \theta_W$$

$$\cong \frac{31\, \omega^3 C_G C_W R_G R_W^2\, (C_G R_G + C_W R_W + C_W R_G)}{15{,}120\, R_W}$$

In order to simplify this expression, the assumption is made that $C_G$ is equal to $C_W$ which is entirely reasonable. Further, in the design of the resistor $R_G$ was made equal to $R_W$. The expression now reduces to

$$\theta_W \cong \frac{93\, \omega^3 C_W^3 R_W^3}{15{,}120}$$

The value of $C_W$ can be computed by use of the formula for the capacitance of a cylindrical capacitor. It was found to be approximately 15 $\mu\mu$f for the 10,000-ohm resistor. For a frequency of 60 cycles, the value of the phase angle due to earth capacitance alone for a 10,000-ohm resistor is

$$\theta_W \cong \frac{93 \times (377)^3 \times (15 \times 10^{-12})^3 \times (10^4)^3}{15{,}120}$$

$$= 1 \times 10^{-15} \text{ radians.}$$

This is the value of the phase angle for one end of the coil grounded. In most cases the resistance will be used with neither end grounded and thus it was necessary to determine what change this will introduce into the value of the phase angle. The series given above shows that the first imaginary term is a function of the ratio of the potentials at the ends of the coil. In order to simulate perhaps the worst case, the assumption is made that $V_0$ is equal to $V_1$, or that their ratio is unity. Now it is seen from the first of the two series, that this has the effect of increasing the imaginary component by a factor of three compared to the value which obtains when $V_0 = 0$. Hence also, the phase angle is increased by the same factor. Under these conditions, the phase angle due to earth capacitance for the 10,000-ohm resistor becomes $\theta_W \cong 3 \times 10^{-15}$ radians.

These theoretical relations show that the ideal method of shielding reduces the effect of earth capacitance to negligible values. The actual phase angle, determined experimentally, is considerably larger than that obtained by these computations. This is easily explained by the fact that the theoretical treatment does not take into account the effects of self-inductance and self-capacitance but only that of the earth capacitance. This method of shielding makes the effect of the latter so small that the effects of self-inductance and self-capacitance become large in comparison. These relations also indicate that the value of $V_0$ can be quite large compared to $V_1$ and yet the phase angle will be negligible. Thus, the ideal method of shielding effectively eliminates from consideration the most troublesome of the three parasitic properties of a resistor, namely earth capacitance.

*Simple Shielding.* For the purposes of comparison it was decided to determine the effect of earth or shield capacitance for a resistor shielded in the manner indicated in Fig. 7A. In obtaining the equation given below the assumption was made that the shield is at a potential equal to that of the midpoint of the resistor within it, or $\left(V_0 + \frac{V_1}{2}\right)$. Capacitance effects from shield to ground and guard circuit to ground were neglected since they are small compared to that of the shield capacitance.

The expression for the impedance of the equivalent circuit shown in Fig. 7A in terms of a power series is

$$Z_W = R_W\left(1 - \frac{1}{12} j\omega C R_W - \frac{1}{120}\,\omega^2 C^2 R_W^2 + \ . \ . \ . \right)$$

The expression for the phase angle of the working circuit is, therefore, $\tan\theta_W \cong \theta_W \cong \frac{1}{-12}\,\omega C R_W$

In order to make the basis of comparison the same $C$ was taken as 15 $\mu\mu$f which is the computed value for $C_W$ for the 10,000-ohm ideally shielded resistor. Thus, the phase angle at 60 cycles due to earth or shield capacitance for a 10,000-ohm resistor shielded as indicated in Fig. 7A is

$$\theta_W \cong -\frac{377 \times 15 \times 10^{-12} \times 10^4}{12} \cong -4.7 \times 10^{-6} \text{ radians}$$

Comparing this with the value obtained for the ideally shielded resistor it is seen that the latter is very much smaller. It will also be noted that for the simple shield the phase angle is negative and will add to the self-capacitance effects of the resistor; whereas in the ideally shielded case, the phase angle due to earth capacitance is positive and will tend to neutralize the self-capacitance. This shows further the effectiveness of the ideal method of shielding.

# A Bridge for Precision Power-Factor Measurements on Small Oil Samples

BY J. C. BALSBAUGH*
Associate, A.I.E.E.

and

P. H. MOON*
Member, A.I.E.E.

AN extensive investigation of the power factor of cable oils and of pure synthetic hydrocarbons was started in June 1930 by the Cable Research Subcommittee of the National Electric Light Association, the work being carried on under the direction of Dr. V. Bush in the Electrical Engineering Research Laboratories of the Massachusetts Institute of Technology. The first step in the research was the design and construction of a suitable bridge for the measurement of power factors of the order of $10^{-4}$ to a precision of one per cent. The purpose of this paper is to describe the bridge and to present the problems involved in the design of a high-precision power-factor bridge. The complete mathematical theory of this bridge will be presented in a final report† to the Cable Research Subcommittee of the National Electric Light Association.

## I. CONSTRUCTION

A study of the various types of bridges showed that the Schering type may be satisfactorily adapted for high-precision power-factor measurements. However, the Schering bridge is not symmetrical; the high-tension arms contain the sample and a fixed condenser respectively, while one low-tension arm contains a resistance and the other a resistance and a variable condenser in parallel. To eliminate the effect of residual capacitances in the low-tension resistances it is necessary to have a variable condenser in one of the high-tension arms for capacitance balancing. Furthermore, the operating flexibility of the bridge is improved by having a symmetrical bridge, that is, similar low-tension arms.

A schematic diagram of the bridge is shown in Fig. 1. The high-tension arms of the bridge consist of a fixed air condenser $C_f$ in one arm and two variable condensers $C_v$ and $C_v'$ in the other arm. The sample $C_s$ can be connected in parallel with $C_v$.

A sectional view of the fixed condenser $C_f$ is shown in Fig. 2. The bridge cylinder is supported from the external shield cylinder by three fused quartz pillars located at each end of the bridge cylinder. This condenser is designed so that (a) a uniform electrostatic field is maintained over the length of the bridge or measuring section, (b) the bridge section is completely shielded, (c) a "grounded" ring is placed between the high-tension and shield sections to prevent leakage currents from entering the shield circuit, and (d) the small amount of solid dielectric is placed where it cannot influence the loss measured by the bridge. The condenser has a capacitance of approximately 86.8 $\mu\mu$f ($86.8 \times 10^{-12}$ farads) and a spacing of approximately 0.25 inch between plates.

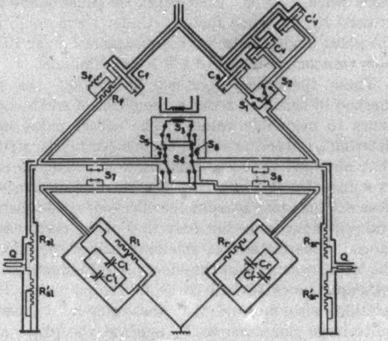

FIG. 1—SCHEMATIC DIAGRAM OF BRIDGE

| | |
|---|---|
| $C_f$ | Fixed condenser 86.8 $\mu\mu$f |
| $R_f$ | Fixed resistance |
| $S_f$ | Shield balancing resistance to compensate for *IR* drop thru $R_f$ |
| $C_v$ | Variable condenser 30-100 $\mu\mu$f |
| $C_v'$ | Variable condenser (Vernier) Approx. 2 $\mu\mu$f. Total change 0.066 $\mu\mu$f |
| $C_s$ | Sample |
| $S_1$, $S_2$ | Disconnecting switches |
| $S_3$, $S_4$ | Reversing switches |
| $S_5$, $S_6$ | Shield balancing switches |
| $R_l$, $R_r$ | Leeds and Northrup precision resistances 0.0—9,999.9 ohms |
| $C_l$, $C_r$ | General Radio precision condensers 1,500 $\mu\mu$f |
| $C_l'$, $C_r'$ | General Radio mica condensers 0—0.1 $\mu$f |
| $R_{sl}$, $R_{sr}$ | Shield balancing resistances (voltage) 0—15,000 ohms |
| $R_{sl}'$ $R_{sr}'$ | Shield balancing resistances (phase) 0—2 ohms |
| Q, Q | 100,000 ohms in series with quadrature voltage |
| $S_7$, $S_8$ | Switches for making single or double shield. Normally closed |

The variable condenser $C_v$ is shown in section in Fig. 3. Small changes in capacitance can be obtained by an axial movement of the inner cone by means of an accurate thread cut on the shaft. Condenser $C_v$ is the larger of the variable condensers and can be varied from approximately 30 $\mu\mu$f to 100 $\mu\mu$f by a 5-inch movement of the internal cone or 200 revolutions of the shaft. Condenser $C_v'$ is similar to $C_v$ and is variable from approximately 1.96 $\mu\mu$f to 2.02 $\mu\mu$f by a 1½-inch movement of the inner cone or 60 revolutions of the

†Progress reports covering the design and construction were presented at periodic intervals to the Cable Research Subcommittee of the National Electric Light Association. A preliminary paper, not published, describing this bridge was presented by the authors at the meeting of the Insulation Committee of the National Research Council at Harvard University in November, 1931.

*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

shaft. The shafts are rotated by means of a crank carried on the operating panel of the bridge. The shafts also carry graduated disks five inches in diameter with one hundred scale divisions and geared Veeder counters to permit accurate readings of the condenser settings. Backlash is prevented by the use of a simple lash lock.

In the low-tension arms, $C_l$ and $C_r$ may be varied through a range of 1,500 $\mu\mu$f by twenty-five revolutions of a crank located on the operating panel of the bridge. This crank carries a graduated dial with one hundred scale divisions and thus one scale division represents 0.6 $\mu\mu$f.

The resistances $Q$ are connected to the primary side of the transformer supplying the bridge voltage. Thus a voltage is obtained across $R_{sl}'$ and $R_{sr}'$ which is in approximate time quadrature with the voltage across $R_{sl}$ and $R_{sr}$ and thereby permits of both phase and magnitude adjustment of the shield voltage.

Circuit connections of the bridge are controlled by switches $S_1$, $S_2$, $S_3$, $S_4$, $S_5$, and $S_6$. Switches $S_1$ and $S_2$ are used in obtaining power-factor measurements by means of a substitution method. Switch $S_1$ connects sample $C_x$ to either the bridge or shield, while switch $S_2$ performs a similar service for $C_s$ and $C_s'$. Switch $S_3$ reverses the connections to the input transformer of the amplifier and galvanometer. Switches $S_5$ and $S_6$ connect the detecting circuit either between bridge and shield or between the diagonal points of the bridge. Switch $S_4$ reverses the low-tension arms of the bridge.

The detecting circuit consists of an input transformer, the shield of the primary winding being at shield potential, while the shield of the secondary winding is at ground potential, a three-stage pushpull amplifier, a band-suppression filter, 57-63 cycles per second, two low-pass filters, 0 to 80 cycles per second, a two-stage amplifier and a vibration and an alternating-current galvanometer. The bridge normally is operated at a frequency of 55 cycles per second. Thus the filter will eliminate the 60-cycle pick-up from other electrical machinery and also prevent harmonics from influencing the measurements. The alternating-current galvanometer is a Leeds and Northrup No. 2470 with a sensitivity of 0.025 microamperes per millimeter deflection.

## II. POWER-FACTOR MEASUREMENTS

The power factor measured by the bridge is

$$P_f - P_x = \omega C_r R_r - \omega C_l R_l \qquad (1)$$

in which $P_f$ and $P_x$ are respectively the absolute power factors of the fixed condenser $C_f$ and combination of condensers in the arm containing $C_v$. Thus to obtain the power factor of an oil sample to a precision of $10^{-6}$ requires the evaluation of the absolute power factor of $C_f$ and $C_v$ to the same precision.

In the past, $P_f$ of equation (1) has been assumed to be zero and the absolute power factor of the unknown has been arbitrarily taken as in equation (1). Our measurements show, however, that when high accuracy is desired such a procedure is in error. Air condensers of the best design have been found to have absolute power factors of the order of $10^{-5}$, and the loss appears to be a surface phenomenon rather than to occur in the body of the gas. This is shown by the following results: the loss varies approximately as the square of the average potential gradient between plates and as the first power of the plate area; the loss depends on the kind of metal used for the condenser plates and also upon the condition of the metal surfaces, being affected by thin layers of oxide, water, or soot on the plates. However, all of the loss does not occur in the metal itself or in the oxide coating since the power factor changes as the air pressure is changed. Furthermore, the power factor is affected by the temperature of the condenser and is reduced by degassing of the condenser surfaces. A more detailed discussion of the absolute power factor of air condensers will be given in a forthcoming paper.

In determining the values of $\omega RC$ in equation (1), obviously the values of $\omega$ and $R$ may be obtained to the desired precision. However, the value of the capacitance in either low-tension arm is more difficult to determine. As shown in Fig. 1 the resistances $R_r$ and $R_l$ and the capacitances $C_r$ and $C_l$ are shielded at ground potential. Consequently the capacitances in the low-tension arms will consist of the condensers $C_r$ and $C_l$ and shunt capacitances to ground. The effect of the shunt capacitances to ground in the resistances $R_l$ and $R_r$ on the power-factor measurement of the bridge may be obtained by considering the capacitances of the low-tension arms to be $(C_l + C_{ls})$ and $(C_r + C_{rs})$ respectively. The capacitances $C_{ls}$ and $C_{rs}$ are the shunt capacitances to ground of the resistances $R_l$ and $R_r$ respectively. Then the power-factor measurement by the bridge as given by equation (1) becomes

$$P_f - P_x = \omega C_r R_r - \omega C_l R_l + \omega C_{rs} R_r - C_{ls} R_l \qquad (2)$$

Equation (2) shows that effect of $C_{rs}$ and $C_{ls}$ on the power-factor measurement by the bridge depends upon their difference. This effect may be decreased by using identical construction and mounting for the two low-tension arms, and by using equal values or $R_l$ and $R_r$. It is also helped by using low values of resistances $R_l$ and $R_r$. However, this will decrease the sensitivity of the bridge.

The effect of $C_{rs}$ and $C_{ls}$ on the power factor measured by the bridge may be eliminated by using a substitution method. Thus in Fig. 1 the bridge is first balanced with the sample $C_s$ connected to the shield by the switch $S_1$. With the bridge arms connected direct and $R_r$ equal to $R_l$, the power factor measured by the bridge is

$$P_f - P_{x1} = \omega C_{r1} R_r - \omega C_{l1} R_l + \omega C_{rs} R_r - \omega C_{ls} R_l \qquad (3)$$

where $P_{x1}$ is the power factor of $(C_{v1} + C_{v1}')$, $C_{v1}$ and $C_{v1}'$ are the capacitances of the variable condensers $C_v$ and $C_v'$ respectively in this balance, and $C_{r1}$ and $C_{l1}$ are the values of the condensers $C_r$ and $C_l$ respectively in this balance. Since $R_l$ is equal to $R_r$, then $C_{v1} + C_{v1}' = C_f$.

If now the sample $C_s$ is connected into the bridge circuit in parallel with $C_v$ and $C_v'$, rebalance of the bridge will require an adjustment of $C_{v1}$, $C_{v1}'$ and either $C_{r1}$ or $C_{l1}$. Assuming $C_{l1}$ is adjusted for balance, then the power factor measured by the bridge is

$$P_f - P_{x2} = \omega C_{r1} R_r - \omega C_{l2} R_l + \omega C_{rs} R_r - \omega C_{ls} R_l \qquad (4)$$

where $P_{x2}$ is the power factor of $(C_{v2} + C_{v2}' + C_s)$, $C_{v2}$ and $C_{v2}'$ are the capacitances of the variable condensers $C_v$ and $C_v'$ respectively in this balance, and $C_{l2}$ is the new value of $C_l$ to obtain balance. In this balance $(C_{v2} + C_{v2}' + C_s) = C_f$.

Subtracting equations (4) and (3) gives

$$P_{x2} - P_{x1} = \omega R_l (C_{l2} - C_{l1}) \qquad (5)$$

Equation (5) shows that the difference in power factors $P_{x2} - P_{x1}$ is independent of the phase angle of the resistances $R_r$ and $R_l$ and depends only upon difference in the capacitance readings of one of the low-tension condensers in the two balances. However, $P_{x2}$ and $P_{x1}$ are power factors of combination of capacitances in the variable high-tension arm of the bridge. It is desired to evaluate the absolute power factor of the sample $P_s$ from equation (5). The capacitance $C_s$ of the sample is equal to

$$C_s = (C_{v1} + C_{v1}') - (C_{v2} + C_{v2}') = C_f - (C_{v2} + C_{v2}') \qquad (6)$$

and

$$C_f = C_{v1} + C_{v1}' = C_{v2} + C_{v2}' + C_s \qquad (7)$$

Let the absolute power factors of the capacitance $C_{v1}$ be $P_{v1}$ and the absolute power factor of the capacitance $C_{v1}'$ be $P_{v1}'$. Then it can be shown that

$$P_{x1} = (P_{v1}) \frac{C_{v1}}{C_f} + (P_{v1}') \frac{C_{v1}'}{C_f} \qquad (8)$$

and

$$P_{x2} = (P_{v2}) \frac{C_{v2}}{C_f} + (P_{v2}') \frac{C_{v2}'}{C_f} + (P_s) \frac{C_s}{C_f} \qquad (9)$$

in which $P_{v2}$ is the absolute power factor of the capacitance $C_{v2}$ and $P_{v2}'$ is the absolute power factor of the capacitance $C_{v2}'$. In general the difference between the capacitance $C_{v1}'$ and $C_{v2}'$ to obtain balance is quite small so that the difference between

$$P_{v1}' \frac{C_{v1}'}{C_f} \text{ and } P_{v2}' \frac{C_{v2}'}{C_f}$$

is negligible. Then the difference between equations (**9**) and (**8**) is

$$P_{x2} - P_{x1} = (P_{v2}) \frac{C_{v2}}{C_f} - (P_{v1}) \frac{C_{v1}}{C_f} + P_s \frac{C_s}{C_f} \qquad \textbf{(10)}$$

Equating (**5**) and (**10**) and solving for $P_s$ gives

$$P_s = \frac{\omega R_l C_f}{C_s} (C_{l2} - C_{l1}) - P_{v2} \frac{C_{v2}}{C_s} + P_{v1} \frac{C_{v1}}{C_s} \qquad \textbf{(11)}$$

The use of the variable condenser in one of the high-tension arms of the bridge permits obtaining a capacitance balance of the bridge when the sample is connected into the bridge circuit by adjusting the variable capacitance instead of the resistances $R_r$ or $R_l$. Thus, it is only necessary to determine the differences in capacitance settings of either $C_l$ or $C_r$. The capacitances $C_l$ or $C_r$ may be calibrated against a standard condenser or as shown in Part V may be calibrated in terms of known power factors.

The precision in power-factor measurement by the bridge is thus dependent upon the accuracy with which the changes in $C_l$ or $C_r$ can be determined. The use of variable high-tension condensers makes it necessary to determine only the difference in the absolute values of different settings of either $C_l$ or $C_r$ instead of absolute values for each setting. For increased precision it would be possible to use a variable condenser of the type shown in Fig. 3 with dimensions such that differences in capacitances for different settings could be obtained to the desired accuracy from the dimensions of the condenser.

## III. Sensitivity of the Bridge

A theoretical treatment of the sensitivity of the bridge has been made by Tschiassny.[12] Defining the sensitivity of the bridge $S_b$ as the reciprocal of the smallest detectable loss angle $\Delta\delta_x$, the sensitivity is

$$S_b = \frac{1}{\Delta\delta_x} = \frac{E}{\Delta e_m} \frac{\omega C_f R_r Z_g}{[(R_l + R_r + R_g)^2 + (\omega L_g)^2]^{1/2}} \qquad \textbf{(12)}$$

in which $\Delta e_m$ is the smallest voltage that can be detected when applied across the input terminals of the amplifier, $E$ is the applied bridge voltage, and $Z_g$, $R_g$ and $L_g$ are the input impedance, resistance and inductance respectively of the amplifier. Thus the sensitivity of the bridge is (a) increased by increase in frequency, (b) inversely proportional to $\Delta e_m$, (c) directly proportional to the applied voltage $E$, (d) directly proportional to the capacitance in the high-tension arms, (e) nearly directly proportional to the low-tension resistances $R_r$ and $R_l$, (f) increased by an increase in the input impedance of the amplifier until $Z_g$ becomes large relative to $(R_l + R_r)$.

The value of $\Delta e_m$ for this bridge may be adjusted to $10^{-8}$ volts. This will give (with $R_l$ and $R_r$ equal to 10,000 ohms, $C_f$ equal to 86.8 μμf, $R_g$ equal to 1,500 ohms, $L_g$ equal to 65 henrys, frequency of 60 cycles and an applied bridge voltage of 1,000 volts) a bridge sensitivity expressed in power factor of approximately $4 \times 10^{-8}$.

## IV. Oil Cell

One type of oil cell that has been developed for this research is shown in Fig. 4. This cell consists principally of high-voltage, measuring and shield cylinders similar to the fixed and variable condensers shown in Figs. 2 and 3. These cylinders are made of nickel. The use of shield cylinders assures an approximately uniform

field in the oil under test and also permits the desired precision in power-factor measurement to be obtained. The use of metal cylinder 13 sealed into the glass tube and connected to shield prevents the glass-conduction and surface-leakage currents from the high-tension lead 26 from entering the bridge circuit and being measured with the power factor of the oil. The cell is designed so that it can be thoroughly evacuated. A coil is mounted around the outer glass tube 1 so that the nickel cylinders may be heated by induction and a gas-free surface obtained. Also the cell is mounted in an oven to permit heating the cell. It is planned to use this cell for tests on pure synthesized hydrocarbons. Some evidence has already been obtained which would indicate that surface effects in the cell have an appreciable influence on the measured power factor of commercial cable oil.

## V. TESTS OF POWER-FACTOR MEASUREMENTS OF THE BRIDGE

One check on the operation of the bridge is obtained by connecting a resistance $R_f$ in series with the measuring section of the fixed condenser $C_f$. In this way the power factor of the fixed condenser is increased by $\omega R_f C_f$. Installing the resistance $R_f$ in series with the fixed condenser requires an alteration of the shield circuit as shown in Fig. 1. The current flowing through the capacitance $C_f$ will also flow through $R_f$, thereby introducing a voltage drop in the bridge circuit. A corresponding voltage drop must be introduced into the shield circuit by the use of $S_f$ so that the bridge circuits on both sides of the resistance $R_f$ will be completely shielded. The value of $S_f$ is obtained by connecting the galvanometer between bridge and shield by means of switches $S_5$ and $S_6$ in Fig. 1 and then adjusting $S_f$ until the galvanometer shows no deflection when the bridge and shield are connected together on the condenser side of the resistance $R_f$.

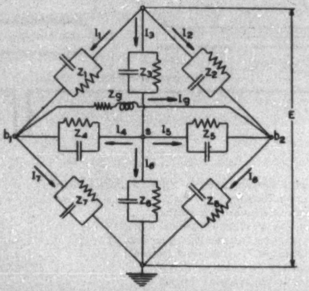

FIG. 5—EQUIVALENT BRIDGE CIRCUIT

The substitution method is used in measuring the increase in power factor of the fixed condenser due to connecting the resistance $R_f$ in series with $C_f$. The bridge is first balanced with $R_f$ equal to zero and then balanced with a definite value of $R_f$ and the change in either $C_t$ or $C_r$ obtained. A number of tests have shown that the measured power factor is well within the desired precision of $10^{-6}$.

## VI. SHIELD BALANCE

A diagrammatic plan of this bridge is shown in Fig. 5. In this diagram "$s$" represents the shield, $Z_4$ and $Z_5$ represent the impedances between the shield and bridge points $b_1$ and $b_2$ respectively, $Z_3$ represents the capacitance from high tension to shield and $Z_6$ represents an impedance for magnitude-balancing and phase-balancing the potential of "$s$" with respect to $b_1$ and $b_2$. Solving for the galvanometer current[28] from Fig. 5 gives

$$\frac{I_g}{E} = \frac{N}{D} \tag{13}$$

where

$$N = Z_1Z_8Z_3Z_4Z_5Z_6\left(\frac{Z_2}{Z_3Z_5}+\frac{Z_7}{Z_4Z_6}+\frac{1}{Z_3}+\frac{1}{Z_4}+\frac{1}{Z_5}+\frac{1}{Z_6}\right)$$

$$- Z_2Z_7Z_3Z_4Z_5Z_6\left(\frac{Z_1}{Z_3Z_4}+\frac{Z_8}{Z_5Z_6}+\frac{1}{Z_3}+\frac{1}{Z_4}+\frac{1}{Z_5}+\frac{1}{Z_6}\right)$$

$$D =$$

$$-\left\{Z_3Z_4Z_5Z_6\left(\frac{1}{Z_3}+\frac{1}{Z_4}+\frac{1}{Z_5}+\frac{1}{Z_6}\right)\Big[Z_1Z_2\,(Z_7+Z_8+Z_g)\right.$$

$$+ Z_7Z_8(Z_1 + Z_2 + Z_g) + Z_g(Z_1Z_8 + Z_2Z_7)\Big]$$

$$+ Z_2Z_3Z_4Z_6Z_8Z_g(Z_1 + Z_7)\left(\frac{1}{Z_3} + \frac{1}{Z_4} + \frac{1}{Z_6}\right)$$

$$+ Z_1Z_3Z_5Z_6Z_7Z_g(Z_2 + Z_8)\left(\frac{1}{Z_3} + \frac{1}{Z_5} + \frac{1}{Z_6}\right)$$

$$\left. + Z_1Z_2Z_7Z_8(Z_3 + Z_6)\,(Z_4 + Z_5 + Z_g)\right\}$$

Equation (13) shows that the bridge is balanced, (that is, $\frac{I_g}{E}$ is zero), for the condition of

$$Z_1Z_8 = Z_2Z_7 \tag{14}$$

and

$$Z_1Z_6 = Z_3Z_7 \tag{15}$$

or

$$Z_2Z_6 = Z_3Z_8 \tag{16}$$

For the relative impedances in this bridge and for the condition of the shield close to balance, the value of $\frac{I_g}{E}$ as a function of $Z_2$ and $Z_1$ and as given by (13) may be closely approximated by

$$\frac{I_g}{E} \cong \left[\frac{Z_2 - Z_1}{Z_1 Z_2}\right]\left[\frac{Z_7}{2Z_7 + Z_g}\right] \tag{17}$$

For the relative values of impedances in this bridge and for the condition of equal ratio arms and the bridge circuit in balance (that is, $Z_1 Z_8 = Z_2 Z_7$) the value of $\frac{I_g}{E}$ as a function of $Z_6$ and as given by (13) may be closely approximated by

$$\frac{I_g}{E} \cong \left[\frac{Z_6}{Z_3} - \frac{Z_7}{Z_1}\right]\left[\frac{Z_7}{2Z_7 + Z_g}\right]\left[\frac{1}{Z_4} - \frac{1}{Z_5}\right] \tag{18}$$

Equation (18) shows that with the bridge circuit balanced and the shield circuit unbalanced, the galvanometer current is proportional to the magnitude or phase unbalancing of the shield and is also proportional to the difference in the admittances between bridge and shield circuit. Thus the closeness with which $Z_6$ must be adjusted for a given precision in power-factor measurement depends directly upon the difference of the capacitances between the bridge and shield circuits. Furthermore it may be noted from a comparison of equations (17) and (18) that with the power factor of $Z_4$ and $Z_5$ equal to zero, a magnitude-unbalance of the shield circuit, that is, a change in the resistance component of $Z_6$, will give a galvanometer current of very nearly the same phase position as a power factor unbalance between $Z_2$ and $Z_1$ with the bridge and shield previously balanced. Similarly a phase unbalance of the shield circuit from balance with the power factor of $Z_4$ and $Z_5$ equal to zero will give a galvanometer current of the same phase position as a capacitance unbalance between $Z_2$ and $Z_1$ with the bridge and shield previously balanced.

Kouwenhoven and Baños[27] have stated that it is advisable to keep the cross-capacitances existing between the measuring and guard circuits low, and also that it is of great importance that the conductances of the cross-capacitances be maintained at zero. However, it should be noted that it is the difference in the cross-capacitances which is of importance to keep small and not their individual magnitudes. Kouwenhoven and Baños[27] have also stated that for the relative impedances in their bridge that phase balancing of the shield is not necessary. This predicates, however, that the phase shifter for bridge balancing must be quite accurately set.

The effect of magnitude and phase unbalancing of the shield circuit with the bridge circuit balanced is shown graphically in Fig. 6. The current $I_p$ shown in Fig. 6 is the galvanometer current per unit bridge voltage for the condition of $Z_1$, $Z_3$, $Z_7$, $Z_8$ as given in Fig. 6 and $Z_2$ equal to 100 $\mu\mu$f and a power factor of $10^{-6}$ and $Z_6$ equal to 5,000 ohms in parallel with 300 $\mu\mu$f. Thus it represents the condition of a power factor unbalance in $Z_2$ and $Z_1$ of $10^{-6}$ with the bridge and shield previously balanced. The current $I_c$ represents a capacitance unbalance of $10^{-4}$ $\mu\mu$f in $Z_2$ and $Z_1$, the remaining conditions being the same as for $I_p$.

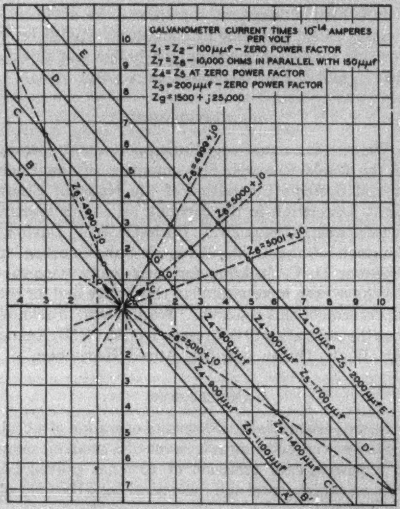

Fig 6—Galvanometer Current for Shield Unbalancing

Current $OO'$ in Fig. 6 represents the galvanometer current in magnitude and phase for $Z_1$, $Z_2$, $Z_3$, $Z_7$, $Z_8$ and $Z_g$ as given in Fig. 6, $Z_4$ and $Z_5$ are equal to impedances corresponding to 600 $\mu\mu$f and 1,400 $\mu\mu$f at zero power factor respectively and $Z_6$ is equal to 4,999 + $j$0. Thus with the bridge circuit balanced and the shield circuit unbalanced in magnitude and in phase the galvanometer current $OO'$ has a component in phase with $I_p$ and $I_c$ and therefore represents an indicated power factor and capacitance difference between $Z_2$ and $Z_1$. For the same conditions except for $Z_6$ equal to 5,000 + $j$0 the galvanometer current is given by $OO''$ and in this case the galvanometer current represents a capacitance difference between $Z_2$ and $Z_1$. With the capacitances between the shield and bridge ($Z_4$ and $Z_5$) having a power factor other than zero the slope of the lines $AA'$, $BB'$, $CC'$, $DD'$ and $EE'$ in Fig. 6 would be changed by approximately the angle of $Z_4$ and $Z_5$. Thus in this case a phase unbalance of the shield will give a galvanometer current with a component in phase with $I_p$, and therefore the bridge would have an indicated power factor although the bridge circuit is balanced. With the bridge constants as given in Fig. 6 the shield is unbalanced in phase by 300 $\mu\mu$f. In the usual bridge the difference between the shield capacitance to ground and the capacitance from bridge points $b_1$ and $b_2$ to ground may be many times this value. This difference in capacitance in combination with a difference between $Z_4$ and $Z_5$ and a power factor of 1 to 2 per cent of $Z_4$ and $Z_5$ can give a power-factor indication in the galvanometer even with the bridge circuit balanced, of several times $10^{-6}$. These results have been checked from the rigorous equation (**13**) and also by experiment.

Another factor of importance in shield balancing is the accuracy with which the phase shifter can be set in the bridge balance. The accuracy of the setting will depend upon the sensitivity of the bridge and the design of the phase shifter. This factor in addition to the effect of difference between $Z_4$ and $Z_5$ makes it advisable to balance the shield for phase when measuring to a precision in power factor of $10^{-6}$.

It is further suggested that it may be advisable to simplify shield balancing by connecting into the bridge, variable condensers between the bridge and shield so that $Z_4$ and $Z_5$ may be made approximately equal.

### ACKNOWLEDGMENT

We wish to acknowledge the support and cooperation of the Cable Research Subcommittee of the Underground Systems Committee of the National Electric Light Association in the carrying on of this research. We also wish to thank Dr. V. Bush, Dr. W. F. Davidson, chairman of the Cable Research Subcommittee and Professor D. C. Jackson, for their many suggestions that have been incorporated in this bridge and for their supervision of this research. We also wish to acknowledge the association in this research of Mr. N. D. Kenney, Mr. W. R. Oppen and Mr. Alfred Herzenberg.

### CONCLUSIONS

Our experience in the design and operation of a bridge for the power-factor measurement of a small oil sample to a power-factor precision of $10^{-6}$ has proved both from an experimental and theoretical basis the following conclusions:

1. Air condensers of usual design may have absolute power factors substantially higher than $10^{-6}$.

2. The measurement of the power factor of an oil sample to a power-factor precision of $10^{-6}$ requires the evaluation of the absolute power factor of the high-tension condensers forming a part of the bridge to a power-factor precision of $10^{-6}$.

3. The use of high-tension variable condensers for capacitance balancing eliminates the necessity of determining absolute values of capacitance of the power-factor measuring condensers.

4. With a single shield circuit, the difference in capacitance between the bridge and shield on the two sides of the bridge determines the accuracy to which the shield must be balanced.

5. It is suggested that variable condensers be installed between bridge and shield circuits so that the difference in capacitance in (4) can be made quite small.

6. The sensitivity of the bridge expressed in terms of power factor should be substantially higher than the desired power-factor precision.

7. The use of ordinary insulations between bridge and shield, the limit in accuracy to which the phase shifter can be set, and relatively large differences in capacitance between bridge circuits and shield, make it necessary to provide phase balancing of the shield circuit.

8. Ordinary insulations may be used between the bridge and shield circuits.

9. The insulation between bridge and shield circuits should be effectively shielded from the high-tension sections.

10. Insulation of shield and high-voltage sections should be to ground.

11. It is suggested that the power-factor measuring condensers be so designed that differences in absolute capacitances may be obtained from dimensions.

12. The power-factor measurement of oil samples to a power-factor precision of $10^{-6}$ requires a study of surface effects in the oil cell and the method of preparing the oil cell for the sample.

## Discussion

### A STANDARD OF LOW POWER FACTOR

(KOUWENHOVEN AND BERBERICH)

### A BRIDGE FOR PRECISION POWER FACTOR MEASUREMENTS

(BALSBAUGH AND SPORN)

**E. S. Lee:** The papers on power factor bridges and reference standards largely trace their A.I.E.E. history back to the year 1925, for in that year there was a paper presented on the testing of cables,[1] which, as far as I can ascertain, was the first A.I.E.E. paper to describe the use of the Schering bridge. That bridge was used for the measurement of cable samples and long lengths at power factor values in the order of 0.005 (0.5 per cent) and results are given in the paper to show that by independent methods the values were in agreement within power factor 0.002 or (0.2 per cent).

Immediately thereafter Schering and other bridges sprang into existence. Between then and today about a dozen papers have been published in the TRANSACTIONS of the Institute, each successive paper showing advance, until today we have the paper by Messrs. Balsbaugh and Moon, stating as their objective a power-factor bridge for the measurement of power factor in the order of 0.0001 (0.01 per cent) to a precision of 0.000001. I take it from the paper that the authors achieved the desired precision, though the attainment of an accuracy figure is not made clear.

The standard described by Messrs. Kouwenhoven and Berberich fills a desired need. It recalls the many things we have done to assure ourselves of the accuracy of our bridges. Comparison of values obtained by others—the use of a calorimeter, measurement by independent methods—all of which have been desired, make a standard of reference very desirable. We wish we might have availed ourselves of the opportunity to use the Kouwenhoven and Berberich standard in measurements with our own bridges, but present conditions have prevented this, as the shipping and packing of such represents a sum which in these days is considered substantial. The usefulness of such a standard is increased considerably if it may easily and cheaply be shipped as a piece of cable, or carried by hand as the standard developed by Mr. Farmer and referred to by Messrs. Kouwenhoven and Berberich.

**J. C. Balsbaugh:** It should first be appreciated that connecting a resistance in series with a condenser increases the power factor of the combination of condenser and resistance by a known amount but does not give any indication of the absolute power factor of the combination. The absolute power factor of the combination is represented by the resistance only when the absolute power factor of the condenser is zero or negligible within the desired precision range. A research project carried on in the Electrical Engineering Department of the Massachusetts Institute of Technology in cooperation with the Cable Research Subcommittee of the National Electric Light Association, involving the study of the power factor of small oil samples with a bridge having an accuracy and precision equal to $10^{-6}$ and a sensitivity that may be adjusted to $10^{-8}$ has shown conclusively that air condensers have absolute power factors which have been found to be as high as $10^{-4}$ and are a function of kind of metal surfaces, voltage gradient and nature of the surfaces.

The method of connecting a resistance in series with a condenser to increase the power factor by a known amount has been used by the writer for several years as a means of checking the calibration of the power-factor measuring condensers. This has been done for power factor ranges of 3 to 5 times $10^{-6}$ and where the accuracy of the shield balance and the dimensions of shielding for the resistance are such that it can be shown that it is not necessary to use an "ideally" shielded resistance.

It can be shown that both the precision and accuracy of a power-factor measurement can quite simply and easily be obtained to a value of $10^{-6}$ and beyond by (a) accurate bridge balancing using a variable high-tension condenser, (b) accurate shield balancing, (c) proper condenser design, (d) measuring power factor in terms of differences in capacitances of one low-tension condenser for different settings through reversal of low-tension arms and use of equal ratio arms with fixed low-tension resistances, (e) evaluation of absolute power factors of high-tension condensers to desired range and (f) use of a proper bridge circuit.

Kouwenhoven and Berberich have made a very interesting design of a condenser and an ideally shielded resistance. However, it should be appreciated that it cannot be used as a standard of power factor in a range where the absolute power factor of the condenser is significant. Even when used in a range where it may justifiably be used as a standard I believe that equal precision and accuracy may be obtained more easily and economically through the use of a proper bridge circuit and a proper method of bridge operation and measurement.

**W. B. Kouwenhoven:** The standard we have constructed is heavy and bulky to ship because in a single unit it embraces both the air capacitor and the ideally shielded resistor. The capacitor like all high voltage air capacitors is necessarily large and heavy. The ideally shielded resistor, however, is small and light and could be easily shipped if desired. It may be used with any air capacitor whose main and guard plates have equal capacitances. In case an air capacitor has a low guard capacitance compared to the main plate, it may be brought up to the one-to-one ratio by connecting a second air capacitor of the proper value in parallel with the guard.

As Mr. Balsbaugh points out, the simple act of connecting a resistance in series with an air capacitor only gives a known increase in power factor but does not tell anything about the absolute value of that quantity. If, however, the capacitor is constructed of the proper metal, is polished, cleaned with alcohol and is operated at low voltage gradients and in a dry atmosphere kept free from dust, its power factor is zero at commercial frequency to within the accuracy of our present day measuring equipment. It is true that there is even then a certain loss caused by the ionization of the air due to radium emanations from the earth and to other sources of ionization. This might be called the inherent power factor of an air capacitor. Its value is very small and Doctor Lemmon and I were not able to detect the ionization current in any of our capacitors at The Johns Hopkins University, using a high voltage continuous current supply and a galvanometer with a sensitivity of $10^{-11}$ amperes per millimeter deflection. If the air capacitor surfaces become tarnished and dust collects on them the power factor is no longer unity. In the limited space in our paper we have pointed out some of the errors that may be introduced by the introduction of a simple series resistance in the air capacitor lead as suggested by Mr. Balsbaugh. We do not recommend this method as the difference of potential between the main and guard leads that results causes a flow of current through the capacitance existing between them. And even if the guard and main lead are brought to the same potential and phase at the bridge corner by means of Mr. Balsbaugh's bridge arrangements that does not mean that they are at the same potential throughout their entire length.

# Laboratory Measurement of Impulse Voltages

BY J. C. DOWELL* and C. M. FOUST†
Associate, A.I.E.E. Member, A.I.E.E.

***Synopsis***—*A brief description is given of impulse generators and the discharge circuit constants involved in obtaining impulse voltages of the desired wave shapes. The relative influences of these constants are recognized and simplified discharge circuits are given. The variations in the wave shape and the reasons for the differences in sparkover values obtained with the three test waves, ½/5, 1/10 and 1½/40, are discussed.*

*The degree of accuracy of the sphere gap for use in measuring impulse voltages is outlined. The resistance-capacitance and the resistance-cable voltage dividers for the connection of the cathode ray oscillograph are described and their operation analyzed in detail. Both dividers are shown to be satisfactory when properly arranged. Data are given showing that the same kilovolts per millimeter on the oscillogram for widely different wave shapes can be obtained.*

*A specimen table for recording of complete test data is suggested which, it is thought, will tend to eliminate a lack of uniformity and completeness in data previously reported.*

## INTRODUCTION

THIS paper treats of the impulse testing of insulation and with the precautions necessary to produce impulse voltages of the desired wave shape. Such testing involves the construction of circuits of the proper electrical constants, the accurate measurement of these constants, the calculation of electrical variations in the circuit and the checking of these calculations by indicating and recording instruments. Confidence in test results obtained accrues to the extent that this rigorous analysis can be accomplished. This paper presents a summary of some recent experiences directed toward this goal.

## METHOD OF OBTAINING IMPULSE VOLTAGES

As early as 1913 a generator producing high voltage impulses of a predetermined wave shape and voltage was developed in the laboratory and used to determine the time lag and impulse ratio of gaps and insulators, and the impulse strength of insulations.[1] Generators of increasingly higher voltages have since been developed[2,3] and a generator for producing 10,000,000 volts has recently been announced by the High Voltage Engineering Laboratory at Pittsfield.

In present practise the voltages used in impulse testing are obtained by discharging high voltage capacitors. These capacitors are first charged directly from transformers or through vacuum rectifier tubes. For low amplitude impulse voltages the capacitor discharges directly through an arranged discharge circuit, for high voltages several capacitors with interconnected spark gaps are charged in parallel and discharged in series.[3,4,5]

The impulse voltages are obtained by connecting the test piece across the resistance through which the capacitor bank discharges. In Fig. 1 is shown a complete discharge circuit with all constants which influence the shape of the discharge wave. In this circuit the test piece is considered as a capacitance. The constant $C_1$ represents the capacitance of the impulse generator on discharge (all the individual units connected in series). The inductance $L$ includes the natural inductance of the total discharge loop plus any inductance that may be added. The constant $C_2$ represents the capacitance of the connected load or test piece such as sphere gaps, insulators, bushings, etc. The two resistances $R_1$ and $R_2$ are added to the circuit to control the front and length of the wave respectively. With the test specimen $C_2$ connected across $R_2$ the ratio of the crest impulse voltage to the initial capacitor voltage is the voltage efficiency of the lightning generator. This efficiency should be high to permit the attainment of the highest possible impulse voltages with a given capacitor bank.

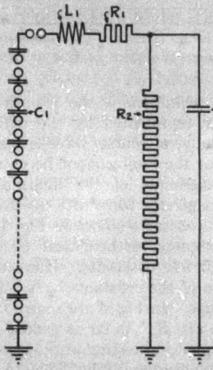

FIG. 1—COMPLETE IMPULSE GENERATOR DISCHARGE CIRCUIT

## METHOD OF OBTAINING SPECIFIED IMPULSE WAVES

Measurement of natural lightning surges[6] in power circuits have shown that the surges which produce damaging effects are of very short time duration (a few microseconds at the most) and practically always unidirectional in polarity. The waves which have been used to greatest extent in the laboratory are unidirectional in polarity (impulses) and have been defined as follows: (½–5), (1–10) and (1½–40). In each case the first figure represents the time-to-crest voltage and the second figure the time-to-half crest on the wave tail in microseconds or millionths of a second, both measured from zero time.

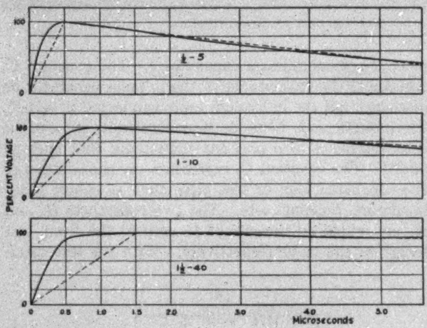

FIG. 2—INPUT VOLTAGE IN USE AT PRESENT

As far as the definitions of the test waves go these three waves are represented by the dotted lines in Fig. 2. Practically, of course, wave shapes with such discontinuities at the crest cannot be obtained. The uninterrupted discharge of the lightning generator capacitor always gives a wave with no discontinuities. The five circuit constants shown in Fig. 1 are always present. A complete mathematical circuit analysis must include all five constants. However, in many instances certain of the constants have little influence on the wave shape. In Fig. 3 are shown two approximate circuits *A* and *B*. As far as general wave shape is concerned in practical testing work either one or the other of these two circuits is relied upon to produce the wave characteristics desired. Both these circuits give wave shapes which are mathematically the difference of two exponentials. As shown elsewhere[4] when the

$$\text{ratio } \frac{T_2}{T_1} = \frac{\text{time to half crest on the tail}}{\text{time to crest}} \text{ is constant}$$

the wave shape is fixed and the same for both circuits *A* and *B*. In Fig. 2 the calculated waves corresponding to the definitions have been plotted in solid lines. It is noted that up to crest value the definitions describe the waves rather poorly. The waves do not rise from zero to crest value at a uniform rate. On the lower part of the wave fronts the kilovolts per microsecond is much greater than it is later when the voltage is approaching the crest value. A large percentage of the total time of the wave front is consumed in rising from 90 per cent to crest. This percentage is greater with the slower waves. This fact causes the chief difference between the three fronts to be near the crest and the three are nearly identical on the first part of the rising front. The waves differ very greatly on the crest and tail. From approximately 0.5 microsecond on, the slow wave has a sustained high voltage within 10 per cent of the actual crest value for 5 or 6 microseconds, compared to 1 microsecond for the fast wave. This fact coupled with the slow voltage decrease to one-half crest value at 40 microseconds as compared to 5 for the fast wave accounts for the low flashover values obtained for the (1½–40) wave. Further, it has been found difficult in several laboratories to produce the 0.5 microsecond to crest with the higher voltage impulse generators and correspondingly longer discharge circuits. The wave obtained requires from 0.5 to 1.0 microsecond to crest. It appears that the different flashover values obtained with the three waves are caused by the flatness of the wave crest and the rate of dropping off of the tail and not by the apparently small differences in wave front.

## METHOD OF MEASURING IMPULSE VOLTAGES

The sphere spark gap[7] and cathode-ray oscillograph[8] are relied upon at present to measure crest voltages and record wave shapes. In tests where the impulse voltage can be repeated the sphere gap when used with proper precautions and corrected for air density can be used to measure crest voltages of impulses within a few per cent. At present the calibration curves which have been adopted include up to 75 cm diameter spheres and voltages up to 1,250 kilovolts crest. There is great need for standardization above this voltage range possibly through 2 meter diameter spheres. As stated above when properly used, the sphere gap is reliable for crest voltage measurements on all the waves being used for practical impulse testing work. That accurate crest voltage measurements on the (½–5) wave are obtained is shown by Fig. 4. This oscillogram was taken with

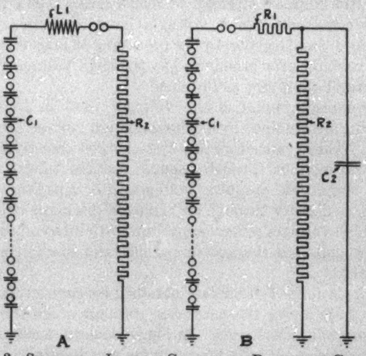

FIG. 3—SIMPLIFIED IMPULSE GENERATOR DISCHARGE CIRCUITS

the crest voltage of the impulse held at the lowest amplitude for flashover. The breakdown, it is noted, is on the crest of the wave and for air breakdown at atmospheric pressure this indicates no time lag.

It happens occasionally that oscillograms are obtained which appear to indicate sphere gap time lag, but such lag can usually be explained in terms of the constants of the sphere gap circuit rather than by the inherent lag in the flashover between the spheres. Various investigators working generally at lower voltages have arrived at a value of $10^{-2}$ microseconds for the inherent time lag of sphere gap breakdown.[9] This order of time lag is not great enough to cause appreciable errors when the crest voltages of the applied waves are being measured. A special problem arises, however, when very high overvoltages with steep front waves are applied to the spheres and the breakdown occurs on the front of the wave. Under these conditions the time lag of the sphere gap is great enough to cause appreciable errors. The magnitude of the error depends upon the per cent overvoltage, the size and spacing of the spheres, and the steepness of the wave front. Such sphere gap characteristics have long been recognized.[1,10]

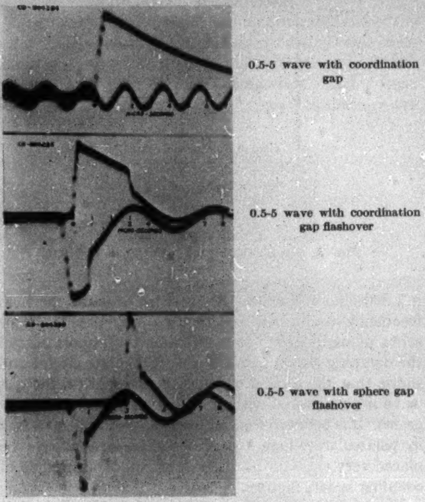

FIG. 4—IMPULSE FLASHOVER OF COORDINATION GAP 0.5–5 WAVE

The cathode-ray oscillograph has been applied to the recording of wave shapes of laboratory lightning with good success. The technique involved is not as yet, however, entirely satisfactory. The problem of time coordination of the oscillograph operation with the impulse generator discharge has been solved with considerable satisfaction in several ways as described elsewhere[4]. The particular remaining problem is that of providing suitable voltage dividers for reducing the impulse voltage to proportions which will permit its application to the cathode-ray oscillograph deflection plates. The ratio of voltage reduction required is of the order of 1,000,000 volts to 1,000, or 1,000 to 1. A proper voltage divider accurately reproduces across the deflector plates of the oscillograph, the impulse wave applied to the test piece, regardless of the shape of the wave used. The ratio of the divider must remain constant regardless of the equivalent frequencies. A divider may reproduce very accurately a smooth wave but tend to dampen out any oscillations that are superimposed on a wave. A thorough study of the characteristics of the divider must, therefore, be made before it can be used with confidence over a wide variety of impulse wave shapes. This is especially essential before using the oscillograph for measuring kilovolts, instead of using the spheres direct.

Two types of voltage dividers have been used to great extent in recent impulse testing work. These types are known as the resistance-capacitance divider and the resistance-cable divider.

The resistance-capacitance divider is shown in Fig. 5. In this divider a capacitance coupling is made near the ground end of the regular discharge resistance, $R_2$, of Fig. 5, to obtain voltage for the deflection plates of the cathode-ray oscillograph. The advantage accruing with this arrangement is that no special tap to the high voltage terminal for the cathode-ray oscillograph is necessary.

The electrical constants of this interconnection between the discharge resistance and the deflection plates must be of such magnitude as will not disturb the true ratio of the discharge resistor as a voltage divider. The portion of the discharge resistor between the tap point and ground has a very low resistance, from 1 to 5 ohms. Currents of a few hundred amperes for the slow waves and several thousand amperes for the fast waves flow through this low resistance. The tap capacitors shown take about two-thirds of the tap voltage, leaving one-third for the deflection plates. The brass tube for elec-

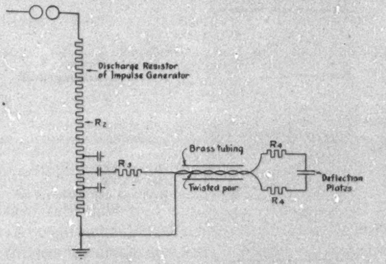

FIG. 5—RESISTANCE-CAPACITANCE VOLTAGE DIVIDER FOR CATHODE RAY OSCILLOGRAPH

trostatic shielding is about 5-ft long and 3-in. in diameter. Capacitance values of this circuit are all of the order of a few micro-microfarads, which capacitance connected across a resistance as low as one to five ohms in the discharge tube preserves a true voltage division. The resistors $R_3$ and $R_4$ are placed in the circuit to dampen its natural oscillation.

Fig. 6 gives a series of oscillograms which show the performance of this type voltage divider particularly with regard to the integrity with which oscillations on the main wave are registered on the oscillogram and the effect of the damping resistors $R_3$ and $R_4$ of Fig. 5. Fig. 6A shows a calculated wave of an approximately (½–5) shape. The capacitance $C_2$ of Fig. 5 in this case consisted of an insulator string and measuring sphere gap in addition to the stray capacitance of the circuit to ground. This capacitance load was sufficient to cause an oscillation of some 8 per cent magnitude superimposed on the fundamental wave shape. Fig. 6B is an oscillogram of this wave shape obtained with zero resistances at $R_3$ and $R_4$. The discharge circuit load oscillation is obscured on this oscillogram by a high frequency oscillation of some 5 million cycles per second. Before taking the oscillogram of Fig. 6C 5,000-ohm resistors were placed at $R_4$. The amplitude of the 5 million-cycle oscillation is greatly reduced. The load oscillation of Fig. 6A is now very clear with about the proper amplitude. The insulator and sphere gap load were removed from the circuit and oscillogram 6D was taken. The load oscillation is not present on this oscillogram and the low amplitude high frequency is still observable. In Fig. 6E a 1,300-ohm resistance was used at $R_3$ and the high frequency oscillation practically disappeared. This series of oscillograms demonstrates the importance of the damping elements in the deflection plate circuit and shows that the oscillations actually present on the test wave are registered with good integrity on the oscillograms. It is believed that for low voltage impulse testing in particular, where the oscillograph can always be placed very close to the discharge circuit this method of coupling is satisfactory.

Fig. 6—Performance of Resistance-Capacitance Divider

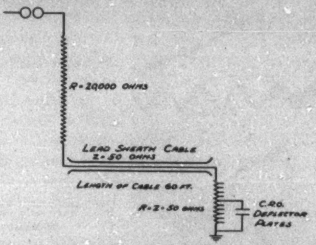

Fig. 7—Resistance-Cable Voltage Divider

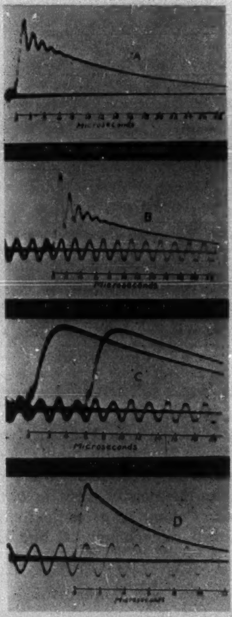
The arrangement of the resistance-cable divider is shown in Fig. 7. It consists of 20,000 ohms of resistance at the impulse generator end, and 50 ohms at the oscillograph end of a lead sheath cable. Both of these resistances are made up of resistance wire non-inductively wound on flat cards. The cable is 60-ft long and acts as a shielded lead from the lightning generator to the oscillograph. The 50 ohms to ground at the oscillograph end of the cable is equal to the surge impedance of the cable. As this resistance is decreased below the surge impedance of the cable reflections occur in the cable which tend to increase the magnitude of any superimposed oscillations and also to decrease the time to reach crest. As this resistance is increased above the surge impedance of the cable the superimposed oscillations are rapidly damped out and the time to reach crest is increased very appreciably. It is very necessary therefore to determine carefully by impulse methods the surge impedance of the cable. If this is not done and the desired value of impedance is not carefully maintained the calibration of the oscillograph deflection will not be the same on the (½–5) and the (1½–40) waves. In Fig. 8A and Fig. 8B can be seen the effect on the magnitude of a superimposed oscillation when the resistance at the oscillograph end of the lead sheath cable is varied. By varying this resistance and holding the same voltage across the test piece, as measured by spheres, with both the smooth wave (Fig. 8c) and the highly oscillatory waves, a value of resistance may be found which gives the same deflection for both waves. When this value of resistance is used the wave shapes recorded check with wave shapes obtained with other types of dividers and also with the calculated wave shapes. Fig. 8D shows a (½–5) wave as taken with the resistance-cable divider.

The 20,000 ohms at the lightning generator end of the cable was chosen to give the desired ratio. If this resistance is increased to a value much in excess of 20,000 ohms a sloping off or lengthening of the faster front waves and a damping of superimposed oscillations are detected. With the (½–5) and (1½–40) waves, no change in the wave shape can be noticed when the resistance is decreased below 20,000 ohms. This resistance is decreased below 20,000 ohms to reduce the ratio of the divider when desired.



D—0-5/5 wave as obtained with resistance-cable divider

FIG. 8—PERFORMANCE OF RESISTANCE-CABLE DIVIDER

A somewhat special problem is involved when high overvoltages are being applied to the test piece, with the steepest front waves obtainable, and it is desired to measure the sparkover voltage with the oscillograph. It is necessary to decrease the divider resistance to far below 20,000 ohms in order that the ratio of the divider does not change. This is due to the extremely high rate of rise of voltage at the time of sparkover on the front of the wave.

Inductance in the divider will cause certain errors at exceedingly steep fronts. All precautions should be taken to secure a non-inductive resistance. If it is found impractical to secure a sufficiently non-inductive metallic resistor, a water tube resistor may be substituted. Another source of error in the divider is the presence of capacitance to ground.

The presence of the cable will introduce an error if it is grounded through a resistance whose value is not equal to the surge impedance of the cable. The losses in the cable may also introduce an error where they are appreciable. However, these errors can be readily predetermined and in our work when they are appreciable, they are taken into consideration. For experiments with circuits in which the resistances of the resistance-cable divider introduces appreciable error, a specially designed capacitance divider is used.

In addition to a demonstration of integrity of registration of wave shape on the oscillograph it is also necessary to show that the oscillograph deflection can be interpreted in terms of kilovolts. It has been the usual practise to refer the oscillograph deflection to sphere gap measurements of voltage across the test specimen. To assure confidence in test results this calibration must be taken as previously described on a fast and on a slow wave. With the same voltage divider and oscillograph connections the kilovolts per millimeter deflection on the (½–5) wave must check that obtained on the (1½–40). This check has been obtained with both the resistance-capacitance type of divider and the resistance-cable divider.

A specimen of data obtained during such an oscillograph calibration is shown in Table I.

TABLE I—VOLTAGE CALIBRATION OF CATHODE-RAY OSCILLOGRAPH

| Wave shape | Type of voltage divider | Impulse voltage kilovolts (corrected) | Oscillograph deflection | |
|---|---|---|---|---|
| | | | Millimeters | Kv/mm |
| ½-5 | Resistance-capacitance | 500 | 47.5 | 10.53 |
| 1½-40 | Resistance-capacitance | 500 | 48.5 | 10.31 |
| ½-5 | Resistance-cable | 593 | 38.6 | 15.35 |
| 1½-40 | Resistance-cable | 594 | 38.7 | 15.35 |

These data show that with properly constructed circuits a consistent calibration may be obtained for different waves and voltage dividers. The necessity of making such tests and obtaining results which check are obvious.

There are, of course, many factors concerned with the arrangement of parts and technique of operation of the generator, test specimen, sphere spark gap, voltage divider and cathode-ray oscillograph which make for incorrect data when they are not carefully considered. At present, space will not permit their consideration. At this time a most important problem is that of tabulation and presentation of data.

## TABULATION AND PRESENTATION OF DATA

No satisfaction will be obtained throughout the field of impulse testing until the various laboratories are able to check results obtained in other laboratories. The most frequent stumbling block encountered in the achievement of this end has been that of inadequate recording and exchange of data. In an effort to improve this situation the authors of this paper wish to present a specimen tabulation, Table II, which they believe will assist greatly if adhered to. The specimen given is taken from a test on square rod coordination gaps.

TABLE II—MINIMUM WAVE FLASHOVER OF COORDINATION GAPS ON POSITIVE POLARITY (½–5) WAVE

| Circuit calibration data | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Coordination gap | | Measuring sphere gap | | | | | | | | | Cathode-ray oscillograph | |
| Circuit rating kv | Gap spacing in. | Sphere diameter cm | Gap setting cm | Cal. curve voltage kv | Impulse generator excit. voltage volts | Dry temp. °C | Atmos. pressure cm Hg | Relative air density | Sphere gap correction factor | True voltage kv | Deflection total mm | Deflection sensitivity kv/mm |
| 69 | 18.75 | 50 | 16.4 | 400 | 46 | 14 | 74.83 | 1.021 | 1.02 | 408 | 26 | 15.7 |
| Column numbers | | | | | | | | | | | | |
| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 |

| Gap test data | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Cathode-ray oscillograph | | | | | Coordination gap corrections for standard conditions | | | | | | | |
| Deflection tap No. | Oscillogram No. | Impulse generator primary volts | Oscillogram deflection at crest mm | Voltage from oscillogram kv | Temp. wet bulb °C | Relative humidity % | Content saturated air at dry temperature gr/cu ft | Content saturated air at relative humidity gr/cu ft | Humidity correction | Total correction humidity and air density | Corrected flashover voltage kv | Date of test |
| 2 | 903740 | 52 | 29.5 | 464 | 7.5 | 35 | 5.227 | 1.83 | 1.058 | 1.037 | 482 | 3–9–32 |
| Column numbers | | | | | | | | | | | | |
| 14 | 15 | 16 | 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 |

It is granted of course that other forms of data presentation may be better adapted to other tests. The principal point is that the data should be as complete as shown in this table. The column headings are in most cases self-explanatory and the testing procedure is somewhat apparent from the table headings and entries. Outlining briefly, the columns, 1 and 2 describe the test piece, column 3 gives the diameter of the calibrating spheres, column 4 the gap spacing of the spheres, column 5 the standard flashover at 25 deg C, 76 cm pressure for this gap spacing. Column 6 gives the impulse generator excitation voltage for the gap flashover as described in columns 3, 4 and 5 but under prevailing test conditions rather than standard conditions. The voltage flashover of the gap must be determined by correcting column 5 to test conditions. Columns 7 and 8 give temperature and pressure readings for making this correction and columns 9 and 10 give the correction factors taken from the accepted tables.[11] Column 11 gives the true voltage obtained at sphere gap flashover. A cathode-ray oscillogram was obtained at this flashover voltage with the gap sparking at the crest of the wave. The maximum deflection of the oscillogram is entered in column 12, and column 11 divided by column 12 gives the oscillograph sensitivity. A similar procedure performed with the test piece substituted for the sphere gap obtains flashover values desired. Column 14 gives the deflection tap number as shown in Figs. 5 and 7 and column 15 the oscillogram number. Column 16 gives the impulse generator excitation voltage for the rod gap flashover and column 17 the oscillograph deflection. The flashover voltage under test conditions is given in column 18. This value must be corrected to standard conditions of temperature, pressure, and humidity. Column 19 gives the temperature of the wet bulb. Column 20 the relative humidity from columns 7 and 19 and a standard humidity chart. Column 21 gives the table value of moisture content of saturated air at temperature of column 7. Column 22 gives the moisture content of the air under test conditions. Column 23 gives the humidity correction as obtained from column 22 and the following tabulation:

HUMIDITY CORRECTION

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| Add | 1.25% | for | (½–5) | wave for each | 1 grain/cu ft | below | 6.5 grains/cu ft |
| " | 1.50% | " | (1 –10) | " " | " 1 " | " | 6.5 " |
| " | 2.33% | " | (1½–40) | " " | " 1 " | " | 6.5 " |

The above correction is subtracted for test values of humidity above 6.5 grains per cu ft.

Column 24 gives the correction factor obtained by combining columns 23 and 9. Column 25 gives the final corrected flashover value at 25 deg C temperature 76 cm of mercury pressure and 6.5 grains per cu ft humidity. Column 26 gives the date of test.

Although vapor pressure in inches of mercury is mentioned in the A.I.E.E. Standards[12] as the unit of absolute humidity, it has become more common to express absolute humidity in terms of grains per cu ft.

Present knowledge of variation of flashover with humidity does not indicate that either reference standard has more significance than the other. Either may be used by obtaining dry and wet thermometer readings and referring to existing tables. The accumulation of laboratory data on flashover and its study with reference to moisture weight and vapor pressure should permit the relative significance of each to be determined.

A tabulation and presentation of data in arrangement and completeness at least as thorough as that given in Table II are necessary if satisfactory checks are to be obtained in several laboratories.

### CONCLUSIONS

In concluding the authors desire to point out again the necessity of careful attention to discharge circuit arrangements, measurement of circuit constants, calculation of discharge wave shapes and cathode-ray oscillograph checks. Great progress awaits the general adoption of this point of view.

Sparkover voltage differences with the (½–5), (1–10) and the (1½–40) waves are believed to be more the result of differences in the wavelength than in the wave front. By definition the waves differ by 8 to 1 in duration and only 3 to 1 in front. Moreover, the waves do not rise uniformly to their crest values, but rise rapidly at first and a large proportion of the total length of the front particularly for the longer fronts is consumed in approaching the crest. The difference in the fronts is, therefore, even less than 3 to 1.

The resistance-capacitance and the resistance-cable voltage dividers are shown to be satisfactory when properly arranged. A carefully adjusted value of cable impedance is required for the resistance-cable divider. It is shown that on a fast or slow wave the calibration of the cathode-ray oscillograph deflection in kilovolts per millimeter can be obtained and will check with either type of voltage divider.

The authors have recognized that an important cause of the disagreements between laboratories is the lack of uniformity and completeness in reporting results of impulse tests. A specimen table form which it is believed will at least suggest the lines along which reports should be made has been presented.

# The Measurement of High-Surge Voltages

BY P. L. BELLASCHI*

Associate, A.I.E.E.

***Synopsis.***—*With the application of surge tests to high voltage electrical apparatus, the question of the measurement of high-surge voltages has become a subject of prime importance. It is accordingly desired in Part I to show the practical work done in the laboratory at Sharon to calibrate the measuring devices, and in Part II to study the more interesting fundamental relationships that affect the operation and accuracy of these measuring devices.*

*The methods of voltage measurement used are the resistance potentiometer, capacity potentiometer, and sphere gap. The potentiometers serve as dividers of the high-surge voltages for measurement at the cathode-ray oscillograph. The resistance potentiometer is a fundamental standard but requires consideration of its limitations for very rapid phenomena. In cases where these can be compensated for or are negligible, the resistance potentiometer method is very desirable. The capacity potentiometer is a secondary standard which can be calibrated. If corona and oscillations can be eliminated, it is a very desirable method of measurement, inasmuch as it is less subject to distorting the wave shape of the surge. The sphere gap is useful as a secondary standard for occasional check measurements, and it is of interest that formulas derived from smaller gaps still hold, as indicated by the check between the calculated curve for the 200-cm sphere gap and the calibration points with the resistance potentiometer.*

* * * * *

## Part I—Laboratory Technique on Measurement of High-Surge Voltages

### METHODS OF MEASUREMENT

THE measurements at the Sharon High-Voltage Laboratory are made by means of a cathode-ray oscillograph, using either a resistance or a capacity potentiometer. A sphere gap also is used to check the readings in some cases, and as a secondary or calibrated standard.

### DESCRIPTION AND CALIBRATION OF THE CATHODE-RAY OSCILLOGRAPH

The type of cathode-ray oscillograph used has been described previously.[1] A complete knowledge of the theory of the oscillograph is not essential, but an understanding of its calibration and the sources of error is necessary in practical operation. For this reason, a brief description of the oscillograph is given, and the essential parts are shown in Fig. 1. It consists primarily of a glass tube, at one end of which the cathode is placed. At the other end of the tube, a perforated plate forming the anode filters the cathode-ray beam, which then passes between deflection plates in the main body of the oscillograph. It can be shown that any electrostatic deflection of the cathode-ray beam is inversely proportional to the cathode voltage, and directly proportional to the field intensity between the plates.[1,2] Therefore, it is essential in using the oscillograph to see that a constant cathode voltage is maintained and as the field intensity between the deflection plates depends on the voltage across the plates and their separation, and if the separation can be varied, care must be taken to keep the setting correct for any calibration. Except for the principle of operation, the cathode-ray oscillograph then does not differ in application from other types of measuring devices. It can be given an individual calibration and used with suitable voltage dividers exactly as in the case of the more common type of oscillograph.

In order to determine the calibration of the oscillograph alone, the arrangement of test shown in Fig. 1 was made. Both negative and positive continuous voltages of different amplitudes were impressed on the voltage plates. These voltages were measured by a calibrated static voltmeter, and the corresponding deflections of the cathode-ray beam measured on oscillograms. These were scaled and the results tabulated, to determine the volts per inch deflection for various voltages and plate settings. The results of these tests showed that the deflections were proportional to the

voltage, and for the plate setting used in calibrating the resistance potentiometer, that 903 volts per inch deflection was obtained, over a test range from 819 to 1,570 volts. A sample oscillogram taken during this calibration is shown in Fig. 2A.

### THE RESISTANCE POTENTIOMETER

The oscillograph cannot be used directly at voltages of 1,000,000 and over used in the laboratory, but some type of voltage divider is necessary to obtain voltages of approximately 1,000 volts for measurement at the cathode-ray oscillograph plates. Further, this must be done in strict proportionality during any interval of time. One of the simplest means is the use of the resistance potentiometer, which is shown diagrammatically in Fig. 3. It consists of two resistances, generally connected by a cable.[12] It can readily be seen that if the voltage is continuous, the potentiometer differs in no way from that commonly used for voltmeter standardization and calibration. If very rapid transients exist and if the resistances have no distributed capacity and no self-inductance, the voltages still will divide proportionately, but it is necessary in order to avoid reflections at the oscillograph end of the cable lead, to have the surge impedance of the cable exactly equal to the resistance at the oscillograph. This is shown in Fig. 2, oscillograms *B*, *C* and *D*. However, if such potentiometers do have distributed capacity, they will not divide the voltage proportionally at all instants, as shown in Part II, and also as indicated by measurements.

FIG. 3—PLAIN RESISTANCE POTENTIOMETER CONNECTED TO CABLE

Terminal-end of cable loaded with proper resistance and connected to voltage deflection plates of cathode-ray oscillograph

In addition to the errors caused by the distributed capacity in the resistance potentiometer, it was found that some errors existed due to effects in the cable. It is therefore desirable to use cable with low distortion and loss effects, and, if possible, of short length. Illustrative of this, oscillograms *B* and *A* in Fig. 4, show the effects in 50 feet of cable against those in 500 feet of cable for similar surges. With the type of cable used at Sharon, to make this error as small as possible, only 42 feet of cable is used.

FIG. 4—OSCILLOGRAMS SHOWING EFFECT OF LENGTH OF CABLE ON SURGE VOLTAGE AT OSCILLOGRAPH AND COMPARISON BETWEEN RESISTANCE AND CAPACITY POTENTIOMETERS

- *B*. Measurement with 50-ft cable (resistance potentiometer)
- *C*. Measurement with capacity potentiometer
- *D*. Oscillogram of 200-cm sphere gap flashover. This oscillogram shows the desirability of using a long, flat wave for the calibration of the sphere gap (resistance potentiometer measurement)

The resistance potentiometer is not suitable for measurements in which the rate of change is more rapid than that to which the potentiometer circuit can respond. It does, however, have the great advantage of being a means of exact quantitative measurement for phenomena not too fast for its response. The resistance potentiometer at Sharon consists of non-inductive, wire wound, oil immersed resistors having a total resistance of 34,000 ohms. The cable lead has a calculated surge impedance of approximately 44.4 ohms. The resistance at the oscillograph is 43.5 ohms, which is close enough to the true cable surge impedance to cause no apparent trouble due to reflection. Since the calibration of the oscillograph was 903 volts per inch, the calibration of the combined oscillograph and resistance potentiometer is $903 \times \frac{34{,}044}{43.5}$ or 707,000 volts per inch deflection.

## SPHERE GAP CALIBRATION

The sphere gap has been used for some time as a standard of voltage measurement. It is, however, a secondary standard, depending upon fundamental calibration made originally by measurements of capacity and current.[3] From studies of sphere gaps, it has been found that their calibration can be represented by formulas which differ slightly in the work of different observers.[4] It was then possible to calculate the calibration of the sphere gap, and this was done. This work was desirable, since the gap at Sharon uses 200-cm spheres, for which no calibration had previously been made. The calculation for the 200-cm sphere gap was made by using the 25-cm sphere gap calibration* and increasing the voltage and spacing scales proportionately to the sphere diameters, and further correcting for the sparking gradient for the two spheres by the proportionality relationship: $\left(1 + \frac{0.52}{\sqrt{a}}\right)$, where $a$ is the radius of the spheres in cm. It was thought possible that the extrapolated sphere gap calibration might not be correct; also that the calibration at low frequency might not be accurate for surge voltages, since the laws of the gap as established by the formula might be changed due to the effect of the surges and also due to their polarity.[5] For these reasons, a check was made between a fundamental calibration with the resistance potentiometer and the calculated calibration.

GENERATOR GROUND

FIG. 6.—VERTICAL CROSS-SECTION OF LABORATORY SHOWING METAL CYLINDERS OR STATIC SHIELDS OF LARGE RADIUS TO ELIMINATE CORONA IN SPACE ADJACENT TO PICK-UP OF CAPACITY POTENTIOMETER

In order to avoid any possible error due to time lag in either the sphere gap or the potentiometer, relatively long, flat-topped waves free from oscillations were employed (1 to 1½-40 waves). Both positive and negative surges were used. Both the points obtained by the resistance potentiometer calibration and the calculated calibration are shown in Fig. 5. A sample calibration point is shown on the oscillogram *D*, Fig. 4. The voltage by sphere gap flashover and the calculated sphere gap calibration indicated 902,000 volts. The deflection of the oscillogram is 1.26 inches, corresponding to 707,000 by 1.26, or 891,000 volts, which checks within 1 per cent. Another sample calibration point shown on oscillogram *B*, Fig. 12, checks within a small fraction of 1 per cent.

This work indicates that the potentiometer and oscillograph readings check the sphere gap indications for waves of duration not too short, and also that this is independent of polarity. Variations from this are found when the phenomena are very fast and the resistance potentiometer cannot respond, or the sphere gap shows time-lag characteristics.

---

*Similar calculations of the 200-cm sphere gap from the present A.I.E.E., 12.5-cm, 50-cm and 75-cm sphere gap calibrations were made, with resultant small percentage variations from the calculated curve here shown. The 25-cm sphere gap calibration was used, as this gap was the one originally calibrated by fundamental measurement.

## THE CAPACITY POTENTIOMETER

The capacity potentiometer, as its name implies, depends on the oscillograph measuring the voltage across a component of capacity. The voltage is here divided inversely as the capacity components. It has certain advantages; for example, it eliminates almost all error due to time delay in response, which is present in the resistance potentiometer, but it is difficult to eliminate inherent oscillations, and care must be taken to keep the capacity relations unchanged. It is used in Sharon, because, due to arrangement of the laboratory, these difficulties could be practically overcome; full advantage of its rapid response could be taken; and because of its desirability where transformer power follow tests were being made, to avoid power currents causing damage to the potentiometer.

FIG. 7—SURGE GENERATOR, 200-CM SPHERE GAP AND SHIELDS

The arrangement of the parts at Sharon is shown in Fig. 6 and is illustrated in Figs. 7 and 8. Other arrangements have been used where the capacities were self-contained, but for lower voltages,[11] and similar arrangements have been and are used in surge distribution tests on transformer windings, where no great difficulty is experienced if all leads are carefully shielded. For high voltage, it is more difficult to provide a separate self-contained potentiometer, and a pick-up as shown in Fig. 6 is used to provide the necessary coupling.

The calibration of the capacity potentiometer was made by taking oscillograms of similar waves by the use of both resistance and capacity potentiometers. The calibration was made using a relatively long, flat-topped wave, as in the case of the sphere gap calibration. The results obtained are shown on Fig. 9.

This calibration is quite interesting, inasmuch as it indicates a linear calibration in volts per inch for the negative waves, but that the deflection increased more than proportionately for the higher positive waves. Also, it was found that on flashover, the negative wave always came to the zero line, whereas the positive waves did not indicate a complete collapse to zero. These phenomena are shown on the oscillograms, Fig. 10. A previous calibration of the potentiometer, when no special provisions were made to eliminate corona, is shown in Fig. 11. In this case, the variation from linear calibration seemed excessive and an effort was made to improve the situation. It is of interest to note that this calibration was made over a period of three months, and does indicate the constancy of the calibration. The discrepancy between positive and negative waves was also found in measurements similarly made in Trafford. It was early believed that the phenomena were due to space charge and in turn due to corona. It was accordingly decided to install metallic cylinders or shields of large radius, with a view to eliminating

FIG. 8—PICK-UP ELEMENT OF CAPACITY POTENTIOMETER

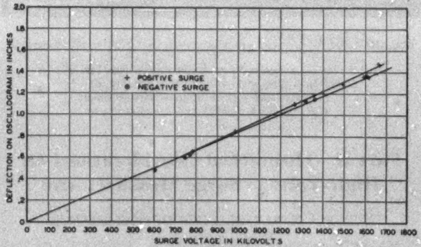

FIG. 9—CALIBRATION OF CAPACITY POTENTIOMETER OBTAINED AFTER INSTALLATION OF STATIC SHIELDS OF LARGE RADIUS; STATIC SHIELDS LOCATED AS SHOWN IN FIG. 6

this space charge in the immediate vicinity in coupling relationship with the pick-up element. How successful this was is shown by a comparison of the calibration curves in Figs. 9 and 11. The arrangement of the shields is shown dotted in Fig. 6. An explanation of the effect of space charge within the scope of this paper is given in Part II.

The successful development of the capacity potentiometer was of advantage because it permitted more accurate reproduction of extremely short surges. A sample comparison of identical surges using the resistance and capacity potentiometers is shown in oscillograms *A*, *B* and *C* of Fig. 4, and in oscillograms *A* and *B* (Fig. 12) at the flashover of the sphere gap. Its other advantage is its freedom from damage due to transformer testing with dynamic power connected.

## Part II—Theoretical Considerations on High-Voltage Surge Measurement

### SURGE CHARACTERISTICS OF RESISTANCE POTENTIOMETER

The circuit in Fig. 3 represents correctly the equivalent circuit of the resistance potentiometer provided the maximum rate of application of the surge voltage *E* with respect to time does not exceed a given limit. It is the purpose here to analyze the maximum surge voltage variation that can be recorded accurately with resistance potentiometers.

The general circuit diagram of the resistance potentiometer is given in Fig. 13. A non-inductive resistance is shown, as the inductance is small and is of secondary importance in the practical problem at hand. A uniformly distributed resistance-capacity network will first be considered, where:

$N$ = total number of resistance elements
$R$ = resistance of each element
$C_1$ = capacity of each element to ground
$C_2$ = capacity across each element
$C_g = NC_1$; $C_e = C_2/N$; $R_o = NR$
$E$ = rectangular surge voltage applied at time $t = 0$
$n$ = number of resistance elements from ground end
$e$ = voltage across then $n$ elements
$p$ = Heaviside's operator $d/dt$

The response of this network is expressed operationally[6] as

$$e = \frac{\sinh \sqrt{\dfrac{RC_1 p}{1 + RC_2 p}}\, n}{\sinh \sqrt{\dfrac{RC_1 p}{1 + RC_2 p}}\, N} E = \frac{E}{F(p)}$$

From the Heaviside expansion theorem, the roots may be found by equating $F(\lambda)$ to zero, which gives

$$\sinh \sqrt{\frac{RC_1 \lambda}{1 + RC_2 \lambda}}\, N = \sinh jk\pi =$$

and $\lambda = -\dfrac{k^2 \pi^2}{R_o (C_g + k^2 \pi^2 C_e)}$, where $k = 1, 2, 3 \ldots$

The steady-state voltage is given as the

$$\lim_{\lambda \to 0} \frac{E}{F(\lambda)} = \frac{n}{N} E$$

and the coefficients of the transient terms are derived from

$$\lambda \frac{d}{d\lambda} F(\lambda) = \frac{\cosh \sqrt{\dfrac{RC_1 \lambda}{1 + RC^2 \lambda}}\, N}{2 \sinh \sqrt{\dfrac{RC_1 \lambda}{1 + RC_2 \lambda}}\, n} \times \frac{\sqrt{\dfrac{RC_1 \lambda}{1 + RC_2 \lambda}}\, N}{(1 + RC_2 \lambda)}$$

Then, from

$$\cosh jk\pi = \cos k\pi \text{ and } \sinh jk\pi \frac{n}{N} = j \sin k\pi \frac{n}{N}$$

and the above expressions, substitution in the expansion theorem gives the final solution:

$$e = \frac{n}{N} E + \frac{E}{\pi} \sum_{k=1}^{k=\infty} \frac{2 \sin\left(k\pi \dfrac{n}{N}\right)}{k \cos(k\pi)} \frac{\epsilon^{-\frac{k^2 \pi^2 t}{Ro (C_g + k^2 \pi^2 C_e)}}}{\left(1 + k^2 \pi^2 \dfrac{C_e}{C_g}\right)} \quad (1)$$

Representative values of the circuit constants $R_e$, $C_g$ and $C_c$ inserted in equation (1) give the voltage-time curves of Fig. 14. These characteristic curves show that if potentiometers are to respond rapidly to abrupt surge voltages, they must have relatively low resistance and small ground capacity. This is also shown in Fig. 15 (*A* and *B*), where calculated curves of response are compared with two typical fast surges. Such discrepancies, as indicated, between fast surges to be measured and the recorded oscillograms have been observed in the laboratory when resistance potentiometers have been used.

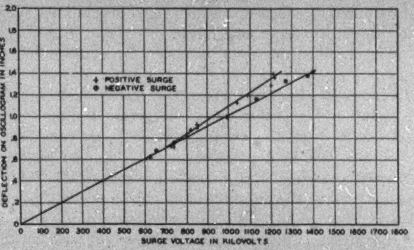

Fig. 11—Calibration of Capacity Potentiometer Without Static Shields (Experimental Results Taken Over a Period of Three Months)

Laboratory arrangement without static shields (see Fig. 6)

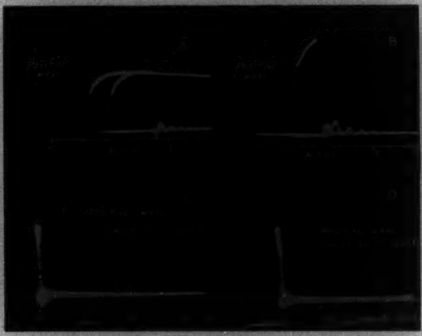

Fig. 12

*A* and *B*. Further comparison of oscillograms using resistance and capacity potentiometers

*A*. Capacity potentiometer measurement, one of the oscillograms showing flashover of 200-cm sphere gap

*B*. Resistance potentiometer measurement showing flashover of 200-cm sphere gap

*C* and *D*. Flashover of positive surges showing the subsistence of the positive space charge for hundreds of microseconds after the collapse of the surge voltage

In practise, the undesirable effect of ground capacity can be materially reduced by locating the potentiometer in a uniform electrostatic field. In the laboratory this can be accomplished by locating the potentiometer resistance in close proximity to the surge generator and extending uniformly to its full height, inasmuch as the voltage distribution from earth to the high potential terminal of the surge generator is practically uniform. It should also be observed that the resistance potentiometer should be connected to the sphere gap through as short a conductor as is physically possible. This method has been used successfully at the Sharon Laboratory, and a degree of response even closer than illustrated in curve *A* of Fig. 14 has been obtained. This is shown by comparing oscillogram *B* in Fig. 12, illustrating a sphere gap flashover measured by the resistance potentiometer, with oscillogram *A*, which shows a similar flashover measured with the capacity potentiometer. It will be noted that oscillogram *A* shows the voltage collapsing immediately upon flashover, whereas in oscillogram *B* the collapse of voltage would appear to require approximately one quarter of a microsecond. Even this is unusually good response for resistance potentiometer. In fact resistance potentiometers as used at Trafford and Sharon are entirely satisfactory for time-lag curve determinations.

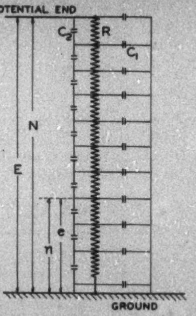

Fig. 13—Circuit of Resistance Potentiometer

(Resistance-capacity network)

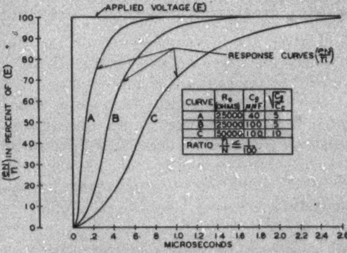

Fig. 14—Response of Resistance-Capacity Network to Rectangular Surge

As shown in Fig. 3, the high resistance component of the resistance potentiometer connects at its low-voltage end through a cable terminated by a resistance. The voltage plates of the cathode-ray oscillograph connect across the terminal resistance. It was stated in Part I that the terminal resistance must be closely adjusted to a value equal to that of the effective surge impedance of the cable, otherwise reflections are superimposed on the surge measured. The ratio of the voltages $e_T'$ and $e_T$, which correspond respectively to reflection and to no reflection at the terminal-end resistance, is readily derived and is given by the expression:

$$\frac{e_T'}{e_T} = \frac{2Z}{R_T + Z} \tag{2}$$

Referring to Table I, the experimental results may be compared to calculated values:

TABLE I

| Film | $R_T$ | $e_T'/e_T$ | |
|---|---|---|---|
| (Fig. 2) | (Ohms) | Calculated | Exper. |
| *B* | 32 | 1.17 | 1.16 |
| *C* | 56 | .88 | .88 |
| *D* | 44 | 1.00 | 1.00 |

Comments: $Z = 44$ (experimental) and $R_o = 34{,}000$ ohms.
$Z = 44$ approx. (calculated).
Length of cable 500 ft.
Time of propagation in 500 ft of cable approximately 1 μsec.

As indicated in equation (2) and Table I, it is essential that $R_T = Z$ for complete elimination of reflections. With a short length of cable of proper characteristics, distortion and attenuation even of steep fronted surges may be reduced to a negligible amount.

## SURGE CHARACTERISTICS OF CAPACITY POTENTIOMETER

Fig. 6 gives the physical set-up of the capacity potentiometer as used at the Sharon High-Voltage Laboratory for the purpose of surge voltage measurement. It is very desirable that the pick-up element of the potentiometer be located in an electrostatic field such that its potential be invariably directly proportional to the surge generator voltage measured irrespective of the amplitude of surge voltage, the polarity of surge voltage, or other effects due to ground.

The theory of the effect of the amplitude and polarity of surge voltages on the operation of the capacity potentiometer is simply and best explained in Fig. 16. Referring to Fig. 16A, where both $h$ and $r$ are here considerably smaller than $d$, the potential at point $p$ is for practical purposes simply expressed as:[7]

$$v_p = \frac{\dfrac{2h}{d} V}{\log \epsilon \dfrac{2d}{r}} = \alpha V \tag{3}$$

The factor $\alpha$ may be termed the reduction ratio of the capacity potentiometer. As shown in Fig. 16C, this coefficient remains constant provided the equal and opposite electric charges remain confined exclusively to the equipotential surfaces of the electrodes. In case the voltage $V$ exceeds a critical value $V_o$, overstress at the surface of the conductor occurs and electrical breakdown of the air adjacent to the conductor takes place.[8] The electrical charge then becomes partly confined to the surface of the conductor and partly distributed as a space charge in the ionized air adjacent to the conductor, increasing the effective radius.

Fig. 17 illustrates the electrical breakdown in the highly stressed region in the air adjacent to the conductor electrode. It is necessary to distinguish between positive and negative surge voltages. Voltages that exceed the disruptive critical voltage $V_o$ are considered.

In the case of a positive surge $V$ applied between conductor and ground, a positive electrostatic field is established in the dielectric, and thus a positive potential is recorded at $p$. Up to the potential $V_o$, for which the gradient at the conductor does not break down the air adjacent, the voltage $v_p$ bears a linear relationship to the surge voltage $V$. As the potential $V$ exceeds the disruptive critical voltage $V_o$, the gradient at the conductor exceeds the ionizing gradient and thus electrical breakdown of the air takes place. As the result of ionization of the air at the conductor, positive ions and electrons are generated. Under the action of the resultant electrostatic field, the electrons move to the conductor. The mobility of electrons is of a much higher order than the mobility of positive ions, so that in a fraction of a microsecond the electrons travel towards the conductor, while on the other hand, the more sluggish positive ions remain practically stationary even for much longer intervals of time. The phenomena, as the surge voltage $V$ rises and exceeds the critical disruptive value $V_o$, consist, as it were, of positive ion streamers forming and spreading out radially from the conductor and electrons moving in rapidly along the streamers to the conductor, as shown in Fig. 17A. Upon collapse of the positive surge, as shown dotted in Fig. 17C, the conductor assumes ground

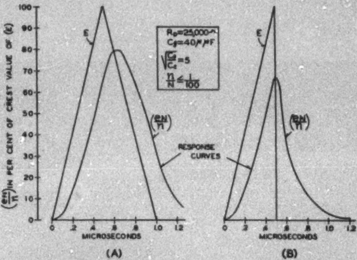

FIG. 15—RESPONSE OF RESISTANCE-CAPACITY NETWORK TO STEEP-FRONTED AND ABRUPT TAIL SURGES

potential through the surge generator circuit. A residual electrostatic field at *p* subsists, which depends on the amount of the positive space charge and the effective capacity of the space charge to the conductor and to earth respectively.

Experimental results with the capacity potentiometer, Fig. 6, show that without conductors of large radius the residual voltage recorded with positive surges is in the order of 10 per cent of the total voltage (oscillogram *A*, Fig. 10). So that, from the fact that the capacity of the space charge to the adjacent conductor surfaces is large relative to its capacity to earth, it stands to reason that for high voltages considerably exceeding the disruptive voltage $V_o$, a large percentage of the charge at the conductor is out in space. The positive space charge subsequently disappears through conduction to conductor and ground, recombination with stray electrons, diffusion, etc., in a time measured in hundreds of microseconds. Oscillograms *C* and *D*, Fig. 12, give the flashover of positive surges and also measure the residual voltage for three to four hundred microseconds after flashover. It should be noted, however, that the collapse of the residual voltage in these films is due partially to the leakage resistance across the voltage deflection plates of the oscillograph.

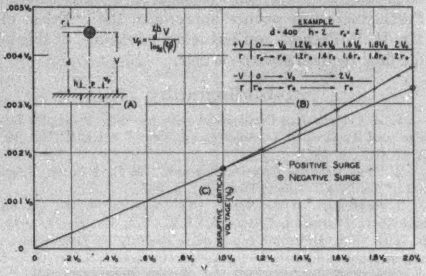

Fig. 16—Surge Potential at Point (*p*) in Electrostatic Field of Long Conductor Parallel to Earth (Dielectric of Medium Consisting of Air at Atmospheric Conditions)

*A*. Voltage $v_p$ at point (*p*) as function of effective radius (*r*) of conductor, spacing (*d*) between conductor and earth, and small distance (*h*) above earth: *V*, surge voltage applied between conductor and earth

*B*. Effective radius of conductor as function of surge voltage *V* above disruptive critical value $V_0$ and of polarity of surge voltage *V*: the variation of the effective radius with the amplitude and polarity of the surge voltage is based on approximate and simplifying assumptions—however, the striking similarity of the calculated curves (*c*) to the calibration curves in Fig. 11 is noteworthy

*C*. Calculated curves of voltage $v_p$ as function of surge voltage *V* and of polarity of *V*

The case of the negative surge *V* is illustrated in Fig. 17B. Above the disruptive critical voltage $V_o$, positive ions and electrons are generated in the air adjacent to the conductor. Under the repelling force of the negative charge on the conductor, and due to their rapid mobility, the electrons move out to the periphery, and a positive space charge is established between the conductor and the negative space charge. Thus equal positive and negative space charges are established so that the electrostatic field set up at *p* cannot be appreciably affected by the presence of the space charges. This is shown in the calibration curves of the capacity potentiometer for negative surges, Figs. 9 and 11. Upon the collapse of the negative surge, the voltage recorded drops closely to zero, as the positive and negative space charges counteract each other in a large measure. Oscillograms *B* and *D* of Fig. 10 substantiate this point.

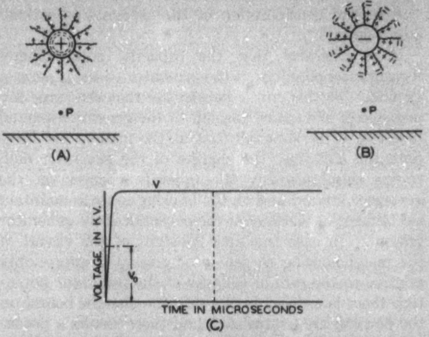

Fig. 17—Positive and Negative Surges Exceeding Disruptive Critical Voltage $V_o$ Applied Between Conductor and Earth

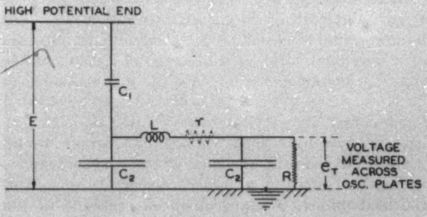

Fig. 18—Equivalent Circuit of Capacity Potentiometer

$C_1$, capacity of pick-up element to the high potential end or electrode

$C_2 + C_3$, combined capacity to ground of lead connecting pick-up element to oscillograph, of the pick-up element and of the deflection plate connecting to lead

*L*, inductance of lead connecting pick-up element to oscillograph

*R*, resistance shunted across deflection plates

Approximate values of circuit constants:

$C_1 = 0.06\ \mu\mu f$: $C_2 = 40\ \mu\mu f$: $L = 1\ \mu H$: $R = 9$ megohms

The above interpretation is in agreement with the corresponding experimental results reported, and also with the recent work of other investigators on the phenomena of surge corona and surge voltage breakdown in air.[9,10] The findings here reported bear out some of the fundamental relationships of surge corona; however, further discussion lies beyond the scope of this paper. The practical results reached bring out emphatically the necessity of large radii of curvature for all parts at high potential particularly those parts closely coupled with the pick-up element of the capacity potentiometer.

A second consideration of the capacity potentiometer follows:

It is desirable that the capacity potentiometer measure the potential of the generator to the generator ground. To this end it is essential that the surge impedance of the entire housing to the generator ground (see Fig. 6) be so small that at the instant the surge potential collapses, the charges of the generator neutralize simultaneously the opposite charges on the generator ground and on the housing so as to maintain the housing at all times at the potential of the generator ground. In case the time constant of the circuit of the metal housing to generator ground is appreciably relative to the rate of collapse of the generator potential, there is a delay in the rate the charges bound on the housing are neutralized, and there results a potential between parts of the housing and ground. These bound charges in turn induce a potential on the pick-up element; oscillations also take place. To eliminate such effects to a minimum, particular care was taken to see that all conducting parts adjacent to the pick-up element of the potentiometer were intimately connected to constitute an integral part of the true generator ground.

Next to consider is the question of response of the capacity potentiometer. In Fig. 18 is represented the equivalent circuit of the capacity potentiometer. The natural period of oscillation of this circuit is in the order of a few hundredths of a microsecond; therefore the capacity potentiometer is capable of responding to very fast surges of this time order. A resistance $r$ of a few hundred ohms or less inserted in the lead connecting the pick-up element to the oscillograph would prevent any natural tendency of the lead inductance to oscillate with the combined capacity to ground of the lead proper, of the pick-up element and of the deflection plate connecting to the lead, but this precaution is necessary only in the case of extremely fast surges of a time duration approaching the natural oscillation of the lead. The purpose of the very large resistance $R$ is to leak off to ground any extraneous charges that would otherwise accumulate across the deflection plate connecting to the lead. In this way the deflection plates are kept in proper condition for surge measurement. This resistance, if not sufficiently large, however, may also neutralize the charges induced on the plates by the surge measured. The rate at which equal and opposite charges on the plates are neutralized is given by the time constant $2C_2 \times R$, which in this case is in the order of several hundred microseconds. Therefore, the capacity potentiometer is capable of responding to extremely abrupt surges in the order of hundredths of a microsecond and, besides, it can respond in strict inverse proportionality of the capacity components even to the very longest surges that are of engineering importance both in laboratory investigations and in commercial surge tests.

## ACKNOWLEDGMENT

The author acknowledges the material aid rendered by Mr. F. J. Vogel in the preparation of this article, particularly on the part relating to the practical work of the laboratory technique. Mention should also be made of Mr. E. J. Grimmer for his assistance in the experimental work at the Sharon High-Voltage Laboratory, and due credit given to engineers of the Trafford High-Voltage Laboratory for experimental investigations there similar in some respects to those at Sharon. Furthermore, the author appreciates the criticism of Mr. H. V. Putman and has taken advantage of this in the final rendering of the article.

Fig. 1

In the development of methods of surge voltage measurement at the Sharon High Voltage Laboratory and also at Trafford, the surge voltage generated and applied to the test piece or apparatus tested has been calculated. The method of calculation is fully discussed in a paper presented before the Institute in June 1932, and the determination of the surge generator constants, constants of apparatus tested, etc., is given in detail in the closing discussion of the same paper[1].

For the purpose at hand let us consider, for example, the case when the surge generator is set up to test point gaps or insulator strings with approximately a ½-5 microsecond wave. The constants of the surge generator circuit and of the test piece are:

$C_s$, capacity of surge generator

$L_s$, inductance of discharge circuit of surge generator

$R_s$, combined inherent and inserted resistance in surge generator

$C_L$, combined stray capacity of surge generator and capacity of test piece

$R$, load resistance of surge generator

$E$ voltage to which surge generator capacity is charged initially

In the left-hand column of Fig. 1 in section *A* is given the equivalent circuit for one arrangement of the surge generator and test piece, and immediately below are tabulated the numerical values of the circuit constants. From the circuit in section *A* and its complete solution[1], the surge voltage applied to the test piece is expressed by the equation in section *B*. This equation is in terms of the initial voltage *E* and of time *t* in microseconds; it is plotted in curve *C*. For the purpose of comparison the measured voltage is given below, oscillogram *Q*. The voltage in oscillogram *Q* is measured by the method described in the paper by the writer.

In the surge generator test-circuit shown in the left-hand column of Fig. 1, the inserted resistance $R_s$ was insufficient to dampen completely the oscillation superimposed on the exponential component of the wave, and therefore this resistance was increased to the appropriate calculated value, given in *A* in the right-hand column. Thus a smooth wave was obtained.

In such calculations full cognizance must be taken of all of the constants of the surge generator circuit and of the test piece or apparatus tested. This is essential if close agreement, as shown in the two examples in Fig. 1, is to be expected between calculated and measured surge voltages. But even with these precautions and care, one will note that as a fundamental method, the calculated surge voltage depends on the correct determination of the initial voltage *E* across the surge generator capacity and on accurately established circuit constants for the entire surge generator and load; and further, that the circuit constants must for the sake of practical calculation be considered as lumped. We have used successfully the complete method of calculation for determining the surge voltage generated, but *the purpose of this calculation is primarily to give further assurance and control over the correct operation of the circuits and is not intended to serve as a fundamental method of surge voltage measurement in itself.*

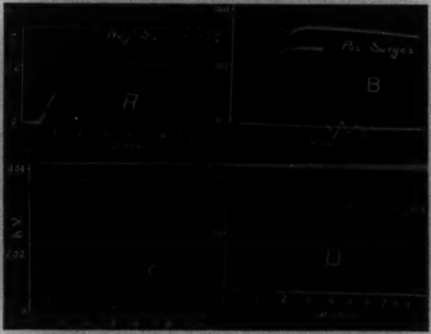

Fig. 2

The laboratories at Trafford and Sharon base the measurement of surge voltages on inherently fundamental methods. The paper presented by the writer describes the method. The resistance potentiometer as used in these laboratories responds with fidelity (both as to wave form and as to constant reduction ratio) to the laboratory waves of ½-5, 1-10, and 1½-40 microseconds. The reduction ratio of the resistance potentiometer is readily calculated from its resistance components. For still more rapid surges than the proposed standard waves, the capacity potentiometer described in the paper by the writer finds useful application. It is of interest to know that the Sharon and Trafford laboratories, each working independently on the time-lag determination of point-gaps, insulator strings, etc., using similar surge waves and methods of correction for air density and humidity, have arrived within experimental error at the same results.

---

[1] *Characteristics of Surge Generators for Transformer Testing*, by P. L. Bellaschi, A.I.E.E. Trans., December 1932, p. 936.

The method of measurement described in Messrs. Dowell and Foust's paper is based on the calculation of the surge voltage from the surge generator circuit and on the sphere gap measurement of the surge voltage crest. The authors lean considerably on Mr. Peek's work. Mr. Peek in his papers[2] calculates the surge voltage generated from the surge generator constants $C_s$, $L_s$ and $R$, and from the initial voltage $E$. In fact, by this method in 1915, Mr. Peek calibrated the 25-cm sphere gap to impulse voltages up to 8-cm gap spacing, and since this calibration apparently checks the 60-cycle calibration he assumed the 60-cycle and impulse calibrations as identical up to the full diameter spacing of the sphere gap[3]. In 1929 Mr. Peek gave the spark-over curve of the 100-cm. sphere gap and the corresponding lightning generator constants ($C_s$, $L_s$ and $R$). On the basis of these calibrations Mr. Peek and his associates have insisted up to the very present on the use of the sphere gap virtually as a primary standard in surge voltage measurement, accepting the present A.I.E.E. calibration curves as applicable to surge voltage measurement.

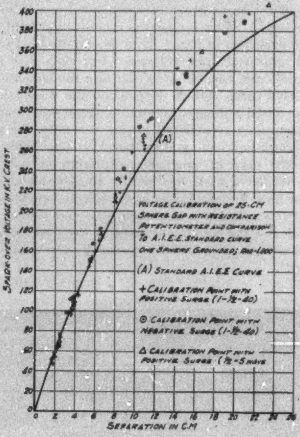

Fig. 3

Now, in the first place, we must bear in mind that in any attempt to calculate the surge voltage from the surge generator circuit and from the initial voltage $E$, at least the refinements outlined in the paper[1] previously mentioned are necessary in order to obtain reasonably correct results, more so if an attempt is made to calibrate sphere gaps to surge voltages from such calculation. We note from Fig. 1 in the paper by Messrs. Dowell and Foust that the surge generator circuit and load are actually being considered now more fully than their associates have done in the past. This is a step in the right direction, as it can be seen that from this circuit the calculated voltage is in accord with the recorded oscillogram (see Fig. 6 of the paper by Messrs. Dowell and Foust). However, if the use of the sphere gaps to measure surge voltages is insisted upon—as Messrs. Dowell and Foust and associates do—then the sphere gaps should be calibrated originally against a true fundamental standard rather than rely for their surge voltage calibration on the round-about method of doubtful rigor stated in the preceding paragraph. The resistance potentiometer, as well as a properly dimensioned capacity potentiometer, for example, lends itself inherently as a fundamental device for such calibration. *It is recommended, therefore, that sphere gap calibrations against a fundamental standard be used in the future and that the limitations of sphere gaps be clearly set forth when these are used as a standard for the measurement of surge voltages.*

### CALIBRATION OF SPHERE GAPS TO SURGE VOLTAGES

The calibration of the 200-cm sphere gap has already been fully described in the paper by the writer. As a further example, the following describes the calibration of the 25-cm sphere gap by the same fundamental method, that is, by the use of the resistance potentiometer.

The following observations are worthy of note: The calibration of the 25-cm sphere gap was made on two individual sphere gaps, in two separate laboratories, by different operators and at different times. Short and long wave surges of positive and negative polarities were used in the calibration. Sample oscillograms of calibration points, including flashovers of the sphere gap, are given in Fig. 2. The results of the calibration are plotted in Fig. 3, where each point represents in general two consecutive oscillograph measurements.

The 25-cm sphere gap was next calibrated to a surge voltage wave somewhat resembling one loop of a 100-microsecond (10 kilocycles) sinusoidal oscillation. This wave rises to crest value in 25 microseconds and recedes to half crest value in approximately 50 microseconds. Sample oscillograms of calibration points and of sphere gap flashovers are shown in Fig. 4. In Fig. 5 are plotted the calibration points obtained with this wave. It may be observed that the purpose of this wave was to calibrate the sphere gap to a surge voltage approaching in effect a single loop of the low frequency commercial voltage (60 cycle).

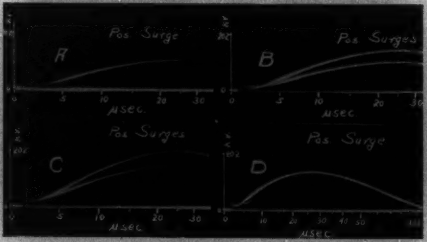

Fig. 4

The calibration points in Figs. 3 and 5 fit a calibration curve which coincides with the present standard A.I.E.E. curve up to approximately 8-cm gap separation but rises well above the A.I.E.E. curve for the wider separations.

The effect of ground and adjacent bodies on the sphere gap calibration was also investigated. Briefly: it is desirable to space the sphere gap at least several sphere diameters from vertical bodies; the grounded sphere may be spaced one to several sphere diameters above ground with no appreciable effect on calibration; the sphere gap behaves erratically at the very wide separation of one sphere diameter, in fact, it is recommended not to use it at gap separations greater than one-half sphere diameter.

[3] A.I.E.E. TRANS., Vol. XXXIV, Part II, p. 1870, Fig. 9; also bottom of p. 1916.

Fig. 6 bears out a point of further interest in the fundamental calibration of the 25-cm sphere gap. This plot gives the relation between the deflection on the film due to the resistance potentiometer and the corresponding deflection due to the capacity potentiometer. The capacity potentiometer is identically the same as described in the paper by the writer, except that in the present case a pick-up element of greater sensitivity was used (2.00-inch deflection with capacity potentiometer corresponds closely to 540 kv). The plot in Fig. 6 confirms the straight line relationship between the surge voltage measured with the resistance potentiometer and the stepped-down voltage measured at the oscillograph. The resistance potentiometer used is approximately 10 feet in length and has a total resistance in the order of 10,000 ohms; this potentiometer responds rapidly even to surges of a fraction of a microsecond duration.

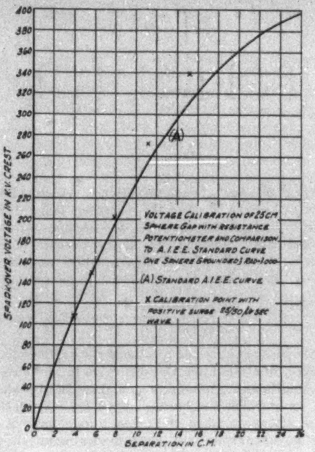

Fig. 5

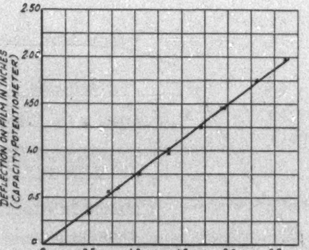

Fig. 6

### Conclusion

The first logical step in an attempt to compare results between the various laboratories is to establish universally fundamental methods of measurement. Comparison of results between different laboratories would then have more significance, apparent differences would be eliminated, and thus the probabilities of a closer agreement enhanced. *To this end we recommend the resistance potentiometer as the fundamental standard. Sphere gaps if used in surge voltage measurement should be checked for their calibration against the fundamental standard. Calculation of the surge voltage from the surge generator test-circuit is useful for control purposes but inadequate as a fundamental method of surge voltage measurement.*

**L. V. Bewley:** The essential elements of an impulse testing set-up are represented in Fig. 7. To develop a proper technique for handling such a complicated circuit, sensitive as it is to errors, is a problem of no mean proportions. Those who have carried on the work have been faced constantly with a multiplicity of vexatious and aggravating problems, among which may be mentioned:

1. The wilful idiosyncrasies of the cathode-ray oscillograph, which entitles it to be called the prima donna of electrical measuring devices.

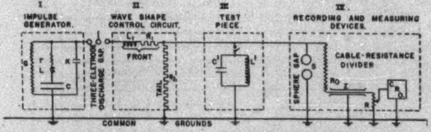

Fig. 7—Equivalent Circuit of Impulse Testing Equipment

I. $C$ = Generator capacitor units, arranged to be charged in parallel and discharged in series
$G$ = Leakage conductance of charging resistors and over-generator frame (permits leakage of charge)
$L$ = Inherent inductance in generator circuit (retards wave front and causes oscillations)
$r$ = Inherent resistance in generator circuit (retards wave front, but not appreciably)
$K$ = Terminal capacitance due to gaps, leads, etc.
II. $L_1$ = Inductance to retard wave front or to introduce oscillations
$R_1$ = Resistance to control front of wave } Depending also on I and III
$R_2$ = Resistance to control tail of wave }
III. $C'$ = Effective capacitance of test piece (affects voltage crest appreciably, depending on I and II)
$L'$ = Effective inductance of test piece (affects wave tail appreciably and introduces oscillations)
IV. $S$ = Sphere gap (measures voltage crests, except for extremely short time-lags)
$R_0$ = Resistance of divider } Determine voltage reduction
$Z$ = Surge impedance of divider }
$R = Z$ = Cable grounding resistor (potentiometer for C.R.O. $R = Z$ prevents reflections)
$CRO$ = Cathode-ray oscillograph

2. Shielding against extraneous electrostatic and electromagnetic fields.

3. Elimination of undesirable oscillations.

4. Securing good fixed grounds common to the complete equipment.

5. Evaluation of the effects of barometric pressure, humidity, temperature.

6. Calculation and predetermination of wave shapes.

7. Determination of the errors in the measuring devices.

The present papers by Foust and Dowell, and Bellaschi are concerned principally with the last of these; and are indicative of the fine work that is being done along these lines. By way of supplement, I wish to discuss the errors of the cable-type divider, and to show that these errors may either be eliminated or compensated for by proper adjustments and technique.

### Errors in Cable-Type Divider

There are four possible sources of error in a cable-type divider connected as in Fig. 8:

1. The terminal resistance $R$ is not equal to the surge impedance of the cable; due both to errors in adjustment and to the fact that a concentric cable is not a true surge impedance invariant to changes of wave shape.
2. Capacitance or other impedance of the measuring circuit.
3. Attenuation and distortion in the cable.
4. Distributed capacitance to ground of the divider resistance.

When the terminal resistance is not equal to the surge impedance of the cable, successive reflections occur; and the voltage across the resistor is given by (ignoring $C$).

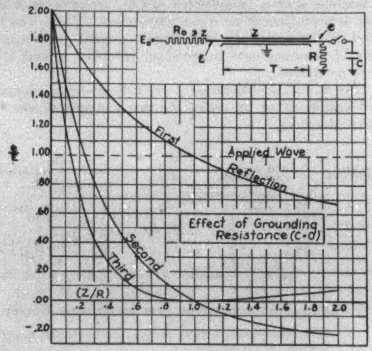

FIG. 8

$$e = \frac{2R}{R+Z}\left\{1 + (a_1a_2)_{2T} + (a_1a_2)_{4T}{}^2 + \ldots\right\}E \qquad (1)$$

where

$$a_1 = \frac{R_0 - Z}{R_0 + Z} \cong 1 \text{ if } R_0 \text{ is very large compared with } Z$$

$$a_2 = \frac{R - Z}{R + Z}$$

$E_0$ = applied wave

$$E = \frac{Z}{R_0 + Z}E_0$$

$T$ = cable length in microseconds

If $R = Z$, then $a_2 = 0$, there are no reflections, and $e = E$. Equation (1) has been plotted in Fig. 8, for the first three reflections, as function of the ratio $(Z/R)$. It is evident that a departure from $Z/R = 1$ leads to the existence of reflections and consequent error.

In Fig. 9 the error of measured wave crest and front is shown for an exaggerated case of $(Z/R = 0.6)$ and $(2T/F = 0.4)$. The effect has been to lengthen the front by 80 per cent and increase the crest by 70 per cent.

In Fig. 10 the effect of increasing the length of the cable (when $R \neq Z$) is shown for a wave which has been chopped on the front. Thus when $2T$ is less than $F$ the reflections pile up and give a measured crest much in excess of the true crest. However, as $2T$ is increased the excess decreases and reaches a constant value for $2T = F$; this residual error being the excess due to the first reflection.

In Fig. 11 the error due to terminal capacitance is shown, when $R = Z$. In this case the voltage is

$$e = \left\{\left[\frac{\alpha}{p+\alpha}\right] + \left[\frac{-p\alpha}{(p+\alpha)^2}\right]_{2T} + \left[\frac{p^2\alpha}{(p+\alpha)^3}\right]_{4T} + \ldots\right\}E$$

and if $E$ is an infinite rectangular wave this integrates to

$$e = E\left\{[1 - \epsilon^{-\alpha t}] - [\alpha t\epsilon^{-\alpha t}]_{2T} + \left[(2\alpha t - \alpha^2t^2)\frac{\epsilon^{-\alpha t}}{2}\right]_{4T} + \ldots\right\}$$

$$= E\left\{\begin{bmatrix}1.000\\ \text{Max.}\end{bmatrix} - \begin{bmatrix}0.368\\ \text{Max.}\end{bmatrix}_{2T} + \begin{bmatrix}0.230\\ \text{Max.}\end{bmatrix}_{4T} + \ldots\right\} \qquad (2)$$

where

$$\alpha = \frac{2}{ZC}$$

Therefore, the *crest* of each reflection is the same for all finite values of $C$, but the *length* of the reflection, being directly proportional to $C$, decreases therewith, and becomes extremely short in practical cases. Thus in Fig. 11 the "length" of the *second reflection* is about $\theta = 5$. If in a practical case $Z = 50$ and $C = 0.0001\ \mu f$ it follows that the length in microseconds is only

$$t = \frac{ZC}{2}\theta = \frac{50 \times 0.0001 \times 5}{2} = 0.0125 \textit{ microsecond}$$

and would pass unnoticed on a cathode-ray oscillogram.

The effect of attenuation and distortion in the cable increases with its length, and is more pronounced for short peaked waves. Thus a wave which has been chopped by a sparkover on its front will attenuate much more than a long wave of the same crest. If no other errors exist in the divider circuit, the measured wave may be several per cent too low for chopped waves. If the amount of this attenuation is known for a given cable, it can be compensated for, approximately, by making a corresponding increase in the ratio $(R/Z)$; but it must be verified that the attenuation is practically constant over the range being investigated.

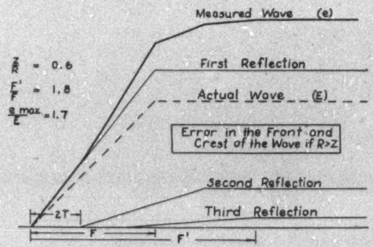

FIG. 9

The divider resistor $R_0$ undoubtedly possesses distributed series and shunt capacitance, as discussed in Bellaschi's paper, as well as series inductance. The question arises as to whether both inductance and capacitance have an appreciable influence, or does the influence of one of them predominate?

Assume in the first place that only capacitance to ground is present, and for the sake of simplicity suppose it lumped at the midpoint of the resistor. Then for a rectangular applied wave the wave entering the cable is

$$E' = \frac{Z}{R_0} E_0 \left( 1 - \epsilon^{-\frac{4t}{R_0 C}} \right) \tag{3}$$

Hence the time constant is $T' = R_0 C/4$, and since $R_0$ and $C$ increase together—*the greater $R_0$ the more retardation of wave front.*

Now if only series inductance is present, in addition to the resistance, the transmitted wave is

$$E'' = \frac{Z}{R_0} E_0 \left( 1 - \epsilon^{-\frac{R_0 t}{L}} \right) \tag{4}$$

Hence the time constant is $T'' = L/R$ and since $L$ does not increase as fast as $R_0$, as extra resistor units are added, it follows that—*the greater $R_0$ the less retardation of wave front.*

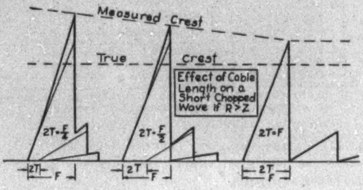

FIG. 10

But the experimental facts agree with criterion (3), which supports Bellaschi's contention of a distributed capacitance. Bellaschi has given the equation and curves for the voltage distribution along the resistor, assuming the constants to be uniformly distributed. The more pertinent information required is a knowledge of the wave shape transmitted to the cable. This is readily arrived at by solving the distributed circuit for current instead of voltage, thus

$$i = \frac{E_0}{R_0} + \frac{E_0}{R_0} \sum_{1}^{\infty} \frac{2\,(-1)^k\, \epsilon^{-\alpha t} \cos\,(k\pi n/N)}{(1 + k^2\pi^2 C_c/C_g)^2} \tag{5}$$

where

$$\alpha = \frac{k^2\pi^2}{R_0\,(C_g + k^2\pi^2 C_c)}$$

The voltage wave entering the cable therefore is

$$E = (Zi)_{n=0} = \frac{E_0 Z}{R_0} + \frac{E_0 Z}{R_0} \sum_{1}^{\infty} \frac{2\,(-1)^k\, \epsilon^{-\alpha t}}{(1 + k^2\pi^2 C_c/C_g)^2} \tag{6}$$

These equations were derived on the assumption that the current in the divider resistor is not affected by the surge impedance $Z$ of the cable, which is practically true because $R_0/Z$ is of the order of 10,000 or more.

Bellaschi remarks on the advisability of mounting the divider resistor close to the generator, and taking advantage of the electrostatic field therefrom to compensate for the capacitance to ground of the resistor. I should think that shielding in that way might be quite a delicate proposition; and possibly subject to considerable electromagnetic induction for heavy discharge currents in the generator. I understand that when the divider happens to be too close to the impulse generator discharge gap that the resistance elements are melted in two by induction; and therefore would infer that a high induction would result from too close proximity to the generator. Of course, trouble from this cause might not be serious except for heavy rates of discharge.

**J. E. Clem:** Mr. Bellaschi goes to some trouble to attempt to demonstrate that the sphere gap is not a primary standard for the measurement of voltages. I fail to see the point in this since it really makes no difference whether the means of measuring voltage is a primary standard, so called, as long as the correct results are obtained. It would be interesting to know just what faith would have been placed in the results of measurements of high impulse voltages made with a resistance cable divider had it not been for the availability of sphere gap data as a check.

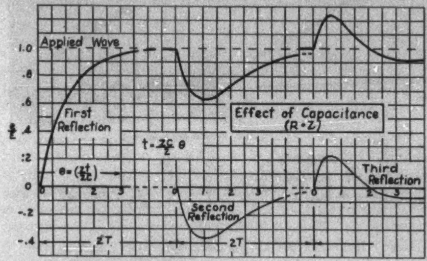

FIG. 11

Fig. 5 of this paper is very interesting since one can draw either of two conclusions from it. Either the sphere gap up to about 1,700 is correct or the resistance cable divider can be made to give correct results up to the same value. This curve further indicates that results obtained in different laboratories up to 1,700 kv upon 1.5-40 microsecond wave should check.

It is known that corona is a serious factor in producing errors in the indications of the resistance cable divider. Since the corona is a function of the voltage and also a function of the rate of change of voltage it is obvious that the corona errors would be greater for the 0.5-5 microsecond wave than for the 1.5-40 microsecond wave. From the author's Fig. 5 it is quite clear that he has been able to eliminate the corona errors for the longer wave up to 1,700 kv. It would be extremely useful if Mr. Bellaschi would show if it is possible to use the resistance cable divider as successfully for the short wave as for the long wave.

FIG. 12

The following discussion of the paper by Messrs. Dowell and Foust is not intended in any way to be a criticism of the material presented. Rather, it is designed to present supplementary data which were obtained during tests to obtain answers to questions which have come to my mind in connection with this work. These questions are briefly as follows:

1. Is there any reason why the cable used in the resistance cable divider should be limited to 150 ft in length?
2. Should we expect to obtain the same kilovolts per millimeter for the 0.5-5 and the 1.5-40 microsecond wave?
3. Should there be any difference in impulse generator excitation for the two waves?

4. Should there be any direct proportionality between the impulse generator excitation and the kilovolts as indicated by sphere gap or cathode ray oscillograph?

5. What polarity effects might be expected?

6. What steps have we taken to make sure that there are no unknown oscillations in the waves and which might cause improper indications of voltage by the sphere gap?

7. Is there any time lag effect on the sphere gaps?

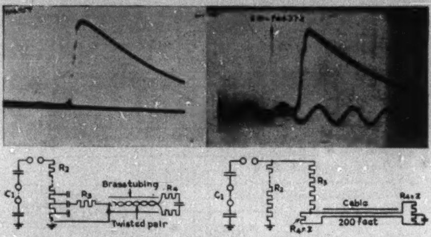

FIG. 13

(LEFT) RESISTANCE-CAPACITANCE DIVIDER COMPARATIVE OSCILLOGRAMS OF ½-5

(RIGHT) RESISTANCE-CABLE DIVIDER IMPULSE GENERATOR WAVE

The results of the investigations made to answer these questions are covered by Figs. 12 to 17:

Fig. 12 is a schematic outline of the impulse generator and discharge circuits as used in this investigation. The excitation voltage of the impulse generator was measured at the point *P* at the left. The cathode ray oscillograph with its divider and the sphere gap are located as indicated.

1. The effect of the length of the cable divider was very carefully studied and the findings may be summarized from the data given in Fig. 13. At the left in Fig. 13 is shown the wave obtained with the resistance capacitance divider and at the right is shown the same wave as indicated by the resistance cable divider. The wave at the left has been verified by calculations based on the circuit constants which were independently determined. The wave obtained by the resistance cable divider using 200 ft of cable is nearly an exact replica of the other wave. It appears then that when the proper precautions are taken there is no reason why the length of the cable divider should be limited to 150 ft.

2. Table I shows the data obtained during this investigation. Under the heading of "Sensitivity" is given kilovolts per millimeter obtained for the 0.5-5 wave and for the 1.5-40 microsecond wave. Tests were made with positive and negative polarity of each case. These data indicate that the kilovolts per millimeter is substantially the same for both waves over the range covered in the tests. It is interesting to note, however, for the difference which exists that if the calibration of the cathode ray oscillograph for the 1.5-40 wave was applied to the deflections given by the 0.5-5 wave the voltage indicated would be higher than that indicated by the sphere gap measurements.

| $R_1$ | 0 | 950 ohms |
| $R_2$ | 450 ohms | 3800 ohms |

3. The impulse generator excitation required for the two waves is given in the center of the table under the heading "Impulse Generator Excitation." Due to the different constants of the circuit the impulse generator excitation efficiency is different for the two waves. When the impulse generator excitation has been corrected for discharge circuit output efficiency, it is found that practically the same excitation is required for either wave.

4. This tabulation also indicates that the impulse generator excitation is practically directly proportional to the voltage as measured by the sphere gap or by the cathode ray oscillograph. This is evident from Fig. 14.

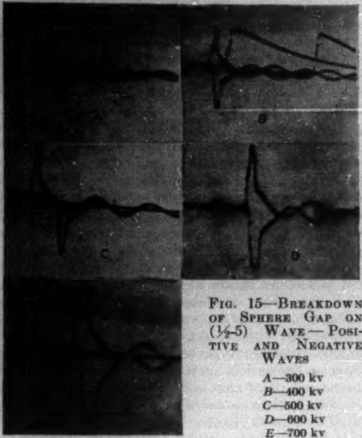

Fig. 15—Breakdown of Sphere Gap on (½-5) Wave—Positive and Negative Waves

*A*—300 kv
*B*—400 kv
*C*—500 kv
*D*—600 kv
*E*—700 kv

5. The effect of polarity is evident from this same tabulation where it is seen that positive polarity voltage for either the short or the long wave required constantly a higher impulse generator excitation. There seems to be no great difference in sensitivity of the cathode ray oscillograph for positive and negative polarities. In Fig. 15 is shown a set of oscillograms taken over a range of voltages with positive and negative voltage applications. There seems to be no difference in the flashover characteristics of the spheres between the positive and negative waves over the range of voltage investigated.

6. In Fig. 16 is shown a set of oscillograms made to demonstrate that only known oscillations are present in the applied voltage. The upper oscillogram shows the wave without any capacitance load. This wave has previously been verified by measurement and by calculations based on circuit constants which were independently determined. In the second oscillogram the capacitance load is due to a 50 cm diameter sphere, as shown. The oscillations appearing on this wave were predicted and checked quite well with the prediction. In the third and fourth oscillograms an increasing capacitance load has been added. In each case the oscillations were predicted and agreed reasonably well with the predictions. Since these small oscillations are only present when they should be and have been predicted and observed it seems very reasonable to believe that no others are present.

Further investigations along this line were made with a much larger capacitance, used so that the oscillation would be of much greater amplitude. These are shown in Fig. 17. In this case also the superposed oscillations were predicted and the predictions agreed quite well with the measured values. Oscillograms are given in which flashover did not occur and in which flashover did occur. It should be noticed that a very slight increase in excitation is required to cause flashover.

7. The sphere gap seems to be showing some time lag at 500 and 600 kv. (See Fig. 17.) At 500 kv a series of films was taken from an excitation of 62 and 57 volts to 65 and 60 volts inclusive. (See Fig. 17.) It was found that an increase in excitation of only 2 volts was sufficient to cause the apparent time lag to disappear, thus indicating that the voltage adjustment giving a time lag for the spheres is very critical, and therefore the error from this source is quite small.

It is very possible that the resistance divider may show polarity effects due to difference in corona at higher voltages and that this same effect might cause the proportionality between excitation and voltage to change, and further, the corona effect might also introduce different errors for the short wave and for the long wave.

It should be noted that all the foregoing tests were made at or below 700 kv, and that 700 kv is pretty well up toward the limit for the 50 cm spheres used in this investigation. Sphere gaps used for impulse voltage measurements should have a lower permissible ratio of spacing to diameter than when used for 60-cycle measurement. With these reservations in mind, the following general conclusions, applicable below 700 kv, may be drawn from the data here presented:

Resistance cable dividers can be made to give correct results with a cable up to 200 ft by the development of proper technique. The longer cable requires more careful adjustment.

The same kilovolts per millimeter for the 0.5-5 wave should be obtained as for the 1.5-40 wave.

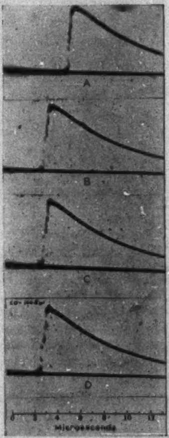

Fig. 16—Impulse Generator Test Wave (½-5) Showing Oscillations Caused by Low Capacitance Loads

*A*—Circuit without capacitance load 700 kv crest
*B*—with 50-cm diam. sphere spark gap load
*C*—with 50-cm gap and 3 pedestal units
*D*—with 50-cm gap and 3 pedestal units and 7 unit

After corrections for discharge circuit efficiency have been made, the same impulse generator excitation should be obtained for the short wave as for the long wave.

Direct proportionality exists between the impulse generator excitation and the output voltage whether the voltage is measured by sphere gap or by cathode ray oscillograph deflection.

Higher impulse generator excitation is required for positive polarity than for negative polarity for both the long and short waves. Over the range of voltage tested there was no appreciable difference in the sphere gap indication or in the kilovolts per millimeter due to polarity.

Study of oscillations indicate that our laboratory has sufficient mastery of impulse test technique that we are sure there are no unsuspected oscillations.

The possible error due to apparent time lag of the sphere gap is quite small, and, in general when sphere gaps are used for measurements of impulse voltages, the range should be more limited than when used for 60-cycle measurements.

**F. D. Fielder:** The paper by Mr. Bellaschi represents much research, and corroborates parallel work at Trafford.

In our capacity divider studies at Trafford, we were handicapped by unfavorable ground conditions. Parts of the capacity system which should remain at zero potential acquired oscillatory voltages of the order of hundreds of volts for short times, thus introducing serious oscillations. These were finally eliminated to a great extent by the use of balanced capacities. Briefly, to the same extent that fluctuations in the ground plate influenced the pickup electrode which was directly connected to the front oscillograph voltage terminal, these influences were balanced with a pickup electrode located behind the ground plate and connected to the rear oscillograph terminal. With this device the waves became recognizable, and the same characteristics of positive and negative calibrations were found as reported in the paper. The same explanations were assigned to the behavior and the same methods of improvement were effective. In general, however, the use of a capacity divider for high voltages is not as suitable at Trafford, because all the apparatus, including the test piece, are close together in the same building, thus introducing complications due to the leads.

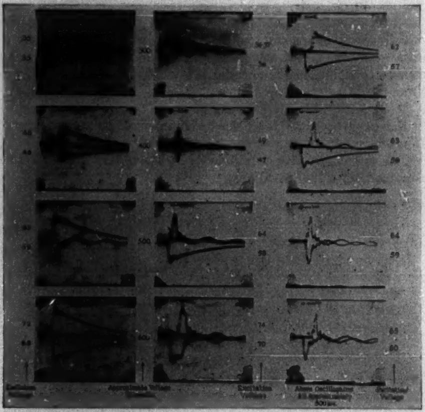

FIG. 17—SPHERE GAP VOLTAGE MEASUREMENTS ON ½-5 WAVE WITH SUPERIMPOSED OSCILLATIONS SHOWING IMPULSE GENERATOR EXCITATION VOLTAGES

In using the resistance cable divider system, it is necessary to have all parts of the system in proper order, as error in any part leads to dissatisfaction with the system as a whole. The use of a poorly insulated cable is an example, for then the wave becomes modified as it is transmitted through the cable. If a poor cable is used it becomes necessary to employ short lengths, thus losing the convenient time delay that a long cable provides. Likewise a resistance unit which has inductance, or which has too great a total resistance, or even too great a resistance per unit length, or which has high capacity to space; all of these factors lead to error and general dissatisfaction. However, a correctly operating resistance divider is trouble free, faithful and consistent. I might suggest that Mr. Bellaschi state more fully the justification for selecting the capacity-to-space values presented in Fig. 14. It would also be interesting to extend this group of curves for resistances lower than 25,000 ohms, since most practical dividers are below this figure.

At present it is believed that resistance divider measurements for all minimum flashover voltages, and for all time lags in excess of one microsecond are reliable. For flashovers at high voltages occurring in shorter times, further improvement will be necessary. Present resistance dividers become inaccurate in this range; capacity dividers with long leads have an undesirable lead effect; capacity dividers with short leads may have variable calibrations because of corona on the leads. The solution for this requirement either is a completely shielded resistance divider, or a capacity divider so constructed that the corona from short leads and a close test piece can have no effect on the capacity relationships. A parallel plate capacity system which is sufficiently large to shield external influences completely has been suggested.

**F. D. Fielder and P. H. McAuley:** We recognize many of the problems in the paper by Messrs. Dowell and Foust which we have encountered, and although some of the solutions are similar, there remain many in which our point of view is different.

We do not agree that suitable voltage dividers for surge measurement are not available. A divider of the type designated resistance-cable in the paper has been used successfully at Trafford for over 4 years. The effects of distributed capacity, of terminal surge impedance and of cable characteristics were investigated and found satisfactory for general surge testing before its adoption. Our experience indicates that if a paper-insulated cable of at least 10,000-volt rating is used, the distortion is negligible even with a length of several hundred feet.

In our studies of different types of voltage dividers it has been found that, unless precautions are taken, resistance dividers tend to lengthen the time to the crest of the wave, and also with short waves the tendency is to reduce the crest values. In general, capacity dividers tend to introduce oscillations of more or less seriousness, and again, unless precautions are taken, a change in the calibration constant is possible. The type of divider designated as resistance-capacitance introduces the undesirable features of both types. We are inclined to question the advisability of using damping resistances in measuring circuits.

The authors completely ignore a valuable check of the accuracy of their measurements. The cathode ray oscillograph has a definite calibration constant for its deflecting plates, usually about 250 volts per centimeter deflection. It depends only on the mechanical design and on the cathode voltage, and can be determined with a high degree of accuracy by taking films with measured d-c voltages on the deflecting plates. Hence, knowing the divider ratio and the oscillograph constant an independent method of voltage measurement is available.

We are pleased to note that the authors have concluded that the rate of rise of standard waves has practically no effect of the flashover values. This was the conclusion we expressed in a discussion[4] at the 1930 Summer Convention, in which we took issue with Mr. Peek's formulas for surge breakdown of apparatus.

In the paper the viewpoint is expressed that the sphere gap is, and has been, the standard of voltage measurement, while the use of the oscillograph presents many problems, in particular concerning the voltage divider. Our viewpoint is exactly the opposite, for we feel that it is vitally important to secure accuracy of the oscillograph, before the sphere gap can be used with confidence. This follows directly from the following facts, which combine to mislead the user of sphere gaps:

1. The natural tendency of any surge generator is to produce waves with superimposed oscillations on the crest of the wave.

---

[4] A.I.E.E. TRANS., October 1930, p. 1502.

2. The tendency of resistance-type dividers is to eliminate or reduce these oscillations.

3. Calculations which neglect certain of the circuit constants also eliminate or reduce these oscillations.

4. Small oscillations on the crest of the wave generally have no effect on apparatus flashover.

5. Sphere gaps, however, detect the full crest of superimposed oscillations, unless they are extremely fast.

6. The relative magnitude of the oscillation or overshooting varies with the capacity of the apparatus under test.

We believe the best way to check results, and to obtain confidence in measuring methods is by direct comparison between different types of voltage dividers; if calculations are to be used at all they should be as rigorous as possible and should neglect none of the circuit constants unless it is proved they have no effect. Calculations should not be submitted as proof that the recorded wave is a replica of the actual wave. This is particularly true when certain of the circuit constants are neglected as suggested by the authors in Fig. 3. Oscillations are due to the series inductance and stray or load capacity. When either is neglected as in Fig. 3, nothing but a smooth wave—the difference of two exponential functions—can be obtained by calculation. Except for showing the approximate front and tail such calculations are of little value. Bellaschi has developed more accurate methods for calculating wave shapes. However, additional oscillations are invariably present on the oscillograms and if overshooting occurs the oscillogram usually shows less than the calculated wave. One feature of oscillograph work which can readily be improved is the wide beams shown in Fig. 4. Assuming 1,000 kv applied these traces are nearly 100 kv wide which limits the accuracy of analysis.

A careful direct comparison of the resistance divider and 500 mm sphere gap has been made recently at Trafford. Fig. 18 shows that the calibration on both positive and negative 1.5-40 waves is different from the A.I.E.E. standard curve. It is appreciated that this statement is based on the assumption that the divider is accurate. However, apart from voltage values, it is far easier to understand a polarity effect on a gap than on a resistance. Similar tests now nearly completed indicate that the 750, 1,000 and 1,500 mm gaps have similar characteristics. This condition has great significance in connection with voltage measurement.

We do not believe the method presented for the determination of the surge impedance of cables is reliable, since it assumes perfect performance of the resistance divider. Bellaschi has shown that such performance is not to be expected for the type of waves illustrated in Fig. 15 of the paper. If the divider is in error then the surge impedance determination will also be in error. We believe a better method is the use of a low voltage surge which can be recorded with the oscillograph as it enters and as it leaves the cable. When these waves are identical the surge impedance is correct.

We would subscribe to the elaborate methods of presenting data if we thought much was to be gained by their use. However, it appears that Table II concerns itself mostly with the application of correction factors which are generally accepted and universally applied. A general statement showing the correction factors used should be sufficient, for it is to be assumed that anyone concerned with surge testing can properly apply the corrections. It is our belief that the causes of the differences between laboratories lie far deeper than simply in the working up of data.

**C. M. Foust:** Mr. Bellaschi's experience with the capacitance voltage divider is very interesting. On first thought, series capacitors always appear to be ideal for obtaining division of high voltages for measurement purposes, particularly for short-time surges. On closer examination, however, many difficulties are revealed. If air dielectric is used as Mr. Bellaschi has done space requirements often make the setup impractical and when measurements appear inconsistent, disturbances in the field between the capacitors are frequently suspected. The polarity difficulty illustrated in Figs. 9 and 11 is one such disturbance. The author chooses to explain this effect in terms of space charge and probably it is clear to many on this basis. The following viewpoint, however, is more significant and may prove helpful to others:

A capacitance voltage divider to hold true ratio must be so arranged that the series capacitor units retain constant capacitance values at all measurement voltages. In neither capacitor must the dielectric break down partially when voltage is applied. If such a partial breakdown occurs in one of the series capacitors, a higher capacitance value is obtained for this unit and an abnormal shift of voltage to the second unit occurs. This shift of voltage with partial breakdown would give the calibration characteristic shown in Fig. 11. It should be present for both polarities but to a much greater degree with positive polarity as the positive breakdown streamers are much greater in extension than negative streamers.

It must be remembered that the actual capacitance coupling values between the high voltage terminal and the pickup antennas connected to the oscillograph plates are very small. With a 1,000 to 1 voltage reduction ratio and an excess capacitance of 1,000 $\mu\mu$f across the deflection plates this capacitance coupling would be only 1 $\mu\mu$f, a very low value and difficult to work with where spacings are so great.

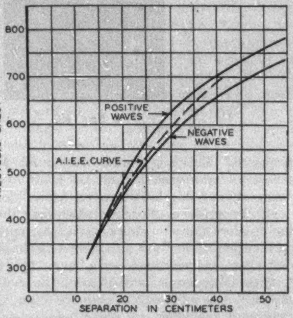

Fig. 18—Calibration Curves for 50-Cm Sphere Gap

One sphere grounded for surge voltages, 1½-40 $\mu$sec waves

The space charge viewpoint I believe of much greater value in connection with the explanation for the oscillograph trace not returning to zero for the positive polarity as shown in Fig. 10.

The use of the large shields effectively reduced the divergence between positive and negative polarity calibration curves. It appears to me, however, that such shields have several important disadvantages. Although the capacitance between the shields and the pickup elements is small still the total capacitance of the shields to ground is large. Such a large capacitance connected to the discharge circuit increases oscillatory effects in the discharge wave and makes it difficult to obtain the more rapid rates of voltage rise across the test specimen.

**C. F. Harding and C. S. Sprague:** Fig. 2 of the paper by Messrs. Dowell and Foust illustrates the relative shapes of calculated waves which conform to the definitions of the proposed standard waves. It is evident that the figures ½, 1, 1½ are scarcely representative of the actual steepnesses of the major part of the fronts of these calculated waves. It would appear to be desirable to define the front of the wave by some more representative figure, perhaps, as has been suggested, by the time between the points on the wave front corresponding to 10 per cent and 90 per cent of the crest value.

The resistance-capacitance divider of Fig. 5 is subject to the same fundamental limitations as is the resistance cable divider of Fig. 7. Of course by tapping off across a low value of resistance, the voltage impressed on the oscillograph circuit is kept low. Consequently the charging current into this circuit may be kept to a very small fraction of the total discharge current thus helping to maintain the proportionality at the higher frequencies and steeper waves. The particular disadvantage of this scheme is that when tapping off the discharge resistor at low potentials, the effect of any induced or stray pickup voltage is proportionally increased. Thus it is absolutely essential that the series capacitance, the resistance $R_3$ and the leads to the oscillograph be extremely well shielded from stray fields.

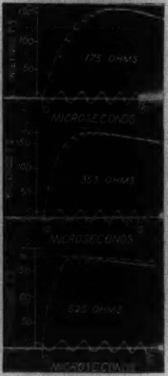

Fig. 19

Fig. 6 provides oscillograms which show the effect of the damping resistors and also of the load capacitance on the oscillations on the front of the wave although, with the slow sweep used, it is difficult to analyze these oscillations. It is desired to point out a source of apparent oscillations on the front of the wave which evidently has not received much attention. In brief, the generator circuit, including any added inductance, has a certain surge impedance, and for a given voltage a corresponding current wave will travel toward the discharge resistance. Reflections then take place across this discharge resistance in a manner entirely analogous to the reflections at the end of a transmission line grounded through various values of resistance, the major difference being that in the case of the generator circuit the distances are much shorter. Hence with a high value of resistance it is possible to get positive reflections and the voltage overshoots across the discharge resistance. With lower resistances negative reflection occurs and the rise of voltage on the front is characterized by the corresponding stair steps. In the usual case the reflections are negative rather than positive. The oscillograms in Fig. 19 were taken with the circuit adjusted to emphasize these negative reflections and to illustrate the progressive changes in these negative reflections as the discharge resistance is increased. These waves, of course, would not be used for testing. The dotted curves indicate the calculated waves. A good agreement is obtained except for the stair steps on the front; this could not be expected when the calculation is based on the assumption of lumped constants. Reflections of this sort will often be combined with oscillations of the generator inductance and load capacitance, and sometimes even with oscillations in the potentiometer circuit. The reflections across the discharge resistance, when present in a noticeable amount, can be detected by comparing their frequency with the length of the generator discharge circuit; an accurate check requires that the wave front be recorded with a sweep noticeably faster than that ordinarily used and for the steeper waves it is necessary that the potentiometer circuit constants be such as will transmit these rapid changes to the deflecting plates, without excessive damping.

Mr. Bellaschi is to be commended on his analysis of the various factors on which depend the strict proportionality of the voltage applied to the deflecting plates of the oscillograph. Quantitative data presented show the distortion due to the use of the resistance-cable divider. These data indicate that, when properly employed, the resistance-cable divider may be used without appreciable error for recording waves, having the average rise of the steepest part of the front taking place in 1 microsecond or more. For faster waves it seems desirable to use the capacitance divider. The latter, of course, must be calibrated by the sphere gap, whereas the resistance-cable divider may be checked both by the gap and by the resistance ratio.

Fig. 4D, apparently indicates a rather serious time lag of the 200-cm sphere gap on a long-tailed, flat-topped wave. This, of course, indicates the necessity of using this type of wave for the purpose of calibrating the oscillograph. In some cases voltages are measured by the sphere gap on waves having breakdown on the front or otherwise having a high peak of short duration. For work of this nature it is necessary that the sphere gap have a negligible time lag. The curves in Fig. 20 illustrate the effect of varying the intensity of ultra-violet light on small spheres at small spacings. The wave used was rather sharply peaked and accentuated the effect of the light in reducing the time lag of the sphere gap. It is reasonable to believe that the use of ultra-violet light on the larger spheres would result in more accurate measurement of the sharply peaked waves.

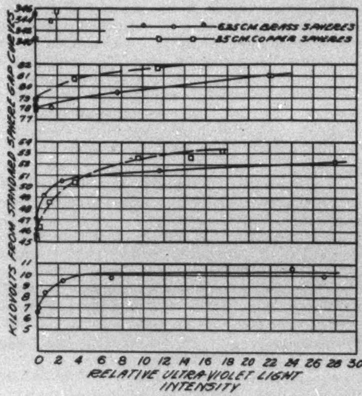

Fig. 20

Taken as a whole the data in this article appear to be in favor of the use of the capacitance potentiometer, assuming the use of the suggested static shields, and providing that oscillations in the potentiometer circuit are prevented by a sufficient, but not too high value of damping resistance.

**E. S. Lee:** Remarkable advances have been made since the year 1925, when papers were presented to the Institute on the subject of surge-voltage measurements, to the present day when papers on the subject are presented for the first time under the auspices of the Committee on Instruments and Measurements. With reference to the Bellaschi paper and the Dowell-Foust paper, I welcome this subject to the auspices of this committee. In this connection there are questions of active interest relative to sphere-spark gap calibration and use, resistance multiplier, voltage dividers, cathode-ray oscillograph performance, and the like, brought up by the report of the lightning and insulator subcommittee that are in the province of the committee on instruments and measurements and in which they should be active in progressing.

In conclusion reference is made to the heritage of the instrument engineer, which is rich. The program today shows prominence in two important fields, which is typical. No engineer advances far before he has to measure something. Thus the instrument engineer finds himself at the outer of all paths. May he continue to realize his responsibilities and the opportunities for his contributions and achievement.

**W. L. Lloyd, Jr.:** The resistance potentiometer and the capacitance potentiometer have both been used to a considerable extent in the Pittsfield High Voltage Engineering Laboratory where the capacitance potentiometer was the first type employed. While the capacitance potentiometer has certain advantages, particularly at the lower voltages where corona can be prevented, it has certain inherent disadvantages at all voltages. If the capacitance potentiometer is inclosed, difficulty is experienced in preventing oscillations on the measured wave and in maintaining the potentiometer and the oscillograph grounds at the same potential. If of open construction, as for example in the potentiometer at Sharon as described by Mr. Bellaschi, it is subject to these same oscillations and, in addition, to changes in the calibration as the capacity relationships between the exposed parts are altered for the different tests.

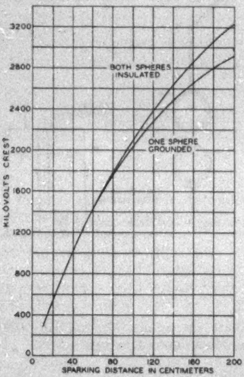

FIG. 21 — CALIBRATION CURVES FOR 200 CENTIMETER SPHERES

Mr. Dowell and Mr. Foust have given in their paper a detailed description of the precautions necessary for the accurate measurement of high voltage, short time impulses. As a result of much painstaking research, it was found possible to obtain accurate oscillograms of the high voltage test-wave and the *same calibration* for either the long or short wave. If the same calibration is not obtained with the 0.5-5 or 1-5 wave as for the 1.5-40 wave it is a clear indication that the oscillograph is not accurately following the voltage being applied to the sphere-gap and test-piece. Either the potentiometer or sphere must be wrong and the accuracy of sphere gap in sparking over without appreciable time lag on the crest of either the short or long wave cannot be questioned. Messrs. Dowell and Foust present data showing that the sphere gap has negligible time lag unless the gap is subjected to very high over-voltages and fronts considerably faster than those of the 0.5-5 or the 1.5-40 waves.

A linear calibration of voltage *vs.* oscillograph deflection is proof that the potentiometer is independent of the rate of voltage rise on the front of the wave. Therefore, changing the test wave from a 1.5 $\mu$sec front to a 0.5 $\mu$sec or 1.0 $\mu$sec front ought to give the same constant value of kilovolts per inch of deflection. Where different calibrations were obtained with the long and short waves, we found that the oscillograph was not accurately following the voltage applied to the sphere-gap and test piece.

Careful adjustments made in the oscillograph potentiometer circuit finally gave the same calibration with the short and with the long wave, and when this was obtained it was found that the oscillograph was truly portraying the impulse wave. Changes made in the lightning generator circuit then resulted in the proper changes in the measured oscillogram and the measured test wave then agreed with the calculated test wave. I would recommend the careful study of the Dowell-Foust paper by anyone planning the accurate measurement of high voltage impulse waves.

Fig. 21 shows the 200-cm sphere gap curve which has been used for a number of years in the laboratory at Pittsfield. It was calculated by means of Peek's sphere gap formula and checked by comparison with the 75 cm and 100 cm sphere gaps for both 60 cycles and impulses.

**F. W. Peek, Jr.:** It is frequently difficult to determine whether a true resistance at low frequency is still predominately a resistance or has become predominately an inductance or a capacitance under transient conditions. For this reason it is futile to argue that any type of divider for measuring impulses is a primary standard. Certain corrections must be made in all cases. Sometimes these corrections are difficult to determine. This is especially so at high voltages where the ratio is high and corona may be a factor. Polarity correction may also be necessary in the oscillograph. It is also futile to argue whether the sphere gap is a primary or secondary standard. This follows because it is sometimes necessary to make corrections in using the sphere gap. For example, for measurements on the rising front of very steep waves it may be necessary to make corrections for time lag although the time lag correction is negligible for the usual waves. However, at very high voltages possible sphere-gap errors are likely to be smaller and corrected with greater certainty than divider errors. In my work I have used the sphere where possible at moderate spacings, generally less than half diameter, thus minimizing corrections for both polarity and time lag. We must always recognize the shortcomings of any instrument and use it in such a way that probable errors are at a minimum.

While the sphere gap probably still is the most useful instrument in general measurements of impulse voltages, in the pioneer work it was invaluable. There was no other method. In fact, practically all of the time lag characteristics now determined by the cathode ray oscillograph were originally determined by the sphere gap in our early work.[5]

**E. J. Wade:** My experience with cathode ray oscillographs in the Lightning Arrester Laboratory at Pittsfield extends back to 1924 and I agree with Mr. Bewley that the idiosyncrasies are legion. However, it is a never-ending source of satisfaction to work with an instrument which, because of its extreme sensitiveness to short time phenomena, continually presents new problems.

One of the major considerations in the operation of the oscillograph is the question of obtaining a really satisfactory voltage divider. The ideal voltage divider would be one with extremely high impedance with a constant and easily measurable ratio and perfect fidelity of reduction. Unfortunately these requirements are incompatible and a compromise must always be made.

---

[5] *The Effect of Transient Voltages on Dielectrics—I*, by F. W. Peek, Jr., A.I.E.E. TRANS., 1915, Vol. 34, p. 1857.

Various designs of air and oil insulated capacity dividers have been used with good results but I have always felt the lack of a direct method of determining the ratio to be a disadvantage. Also while the fidelity of reduction is unquestioned the addition of any capacity across the test piece is undesirable with some circuits, particularly where the current following breakdown is being measured.

Another voltage divider which we have found very useful is what we call the compensated resistance divider, where capacity is added to balance the error caused by the capacity of the deflecting plate circuit. One form of this divider was described by K. B. McEachron in *Electric Light and Power*, May 1929, and it is also considered mathematically by Peters, Hannen and Blackburn.[6] The advantage of this type of voltage divider is that the ratio can be accurately predetermined and the impedance made very high. Unfortunately it must be used close to the oscillograph as the introduction of a cable prevents the use of the compensating capacity.

The cable divider probably is the most widely used and valuable type of divider. Although it cannot perfectly b ecompensated the error can be made so small as to be negligible in most cases. The capacity divider and cable divider have been checked one against the other, both in the laboratory and during field tests. With either divider the connection to the oscillograph is of importance, the ground lead to the oscillograph and deflecting plates being kept as short and direct as possible, to avoid inductive drop.

**J. C. Dowell and C. M. Foust:** Mr. Bellaschi feels that the authors are appreciably in error by using the sphere gap to measure surge voltages. We would like to call attention to Fig. 5 in Mr. Bellaschi's paper showing a voltage calibration of the 200-cm sphere gap with the resistance potentiometer together with the calculated curve for the sphere gap. This apparently is a perfect check of the 200 cm sphere gap on the 1½-40 μsec wave, and it would seem that this behavior of the sphere gap would allay any criticism of its accuracy on this wave. The authors have found no appreciable difference in the operation of the sphere gap between the ½-5 and the 1½-40 waves.

While apparent time lags are occasionally recorded on oscillograms as Mr. Bellaschi has shown in Fig. 4D, it has been demonstrated by the authors that this time lag occurs only at the very minimum breakdown voltage and a very slight increase will cause it to disappear. In a sphere gap voltage calibration obtained by the authors the sphere gap is adjusted through the range from 0 to 100 per cent arcing. The mid point of this range or the 50 per cent arcing point is chosen and this is independent of the apparent time lag as mentioned above.

If by chance the sphere gap should have a time lag characteristic it would require a higher voltage to arc over a given spacing with the ½-5 wave than with the 1½-40 wave, the same as is experienced with the rod gap but to a lesser degree. Then in measuring a given applied voltage on the ½-5 wave the sphere would have to be closed down to a smaller spacing to obtain 50 per cent arcing than would be necessary if the sphere did not have a time lag. Reading the equivalent voltage from the calculated curve for this smaller spacing gives a smaller voltage than would be obtained if the sphere had no lag. Since the sparkover voltages of insulators and rod gaps for the ½-5 μsec wave obtained by the authors with the aid of the sphere gap are very appreciably higher than values obtained by other laboratories, it seems preposterous to try to explain the difference by inaccuracy of the spheres on the shorter waves since any such error would be in the wrong direction.

Mr. Bellaschi recommends that the resistance potentiometer be used as the "fundamental standard" for measuring impulse voltages. The authors' views on this point are clearly set forth in Mr. Peek's discussion. We feel that the true ratio of the resistance potentiometer is not necessarily the ohmic ratio and that it should not be relied upon as a fundamental standard for measuring kilovolts. From data that have been obtained we have reason to believe that corona affects the ratio of the resistance divider and that this effect is different for the two polarities.

Mr. Fielder and Mr. McAuley suggest an inaccuracy in the method used to measure the surge impedance of cables on account of errors in the divider for the type waves that were used. If the resistance divider cannot be made to reproduce correctly a wave with a superimposed oscillation we do not understand how it can be used with confidence in measuring kilovolts.

The authors are somewhat puzzled over Mr. Bellaschi's hesitancy regarding the use of the complete discharge circuit analysis for voltage measurement in view of his eagerness to make a strong case for the resistance voltage divider. The authors did not recommend discharge circuit analysis as a method of voltage measurement or the use of a resistance divider not checked against a sphere gap for such measurements. As pointed out by Mr. Fielder all parts of the resistance-cable divider must be in proper adjustment. High loss cable, inductance in the resistance unit, too great resistance per unit length, high capacity to space and corona all prevent good divider performance. These and others also are the identical problems which must be met in discharge circuit analysis. It easily follows, therefore, that performance of the resistance divider is quite as difficult to anticipate as that of the discharge circuit.

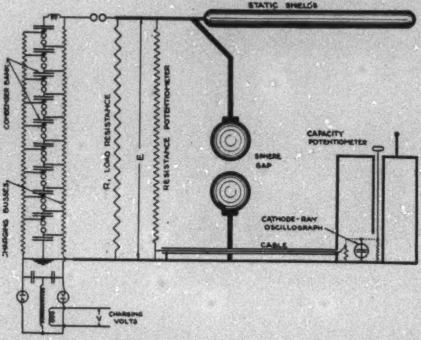

FIG. 22—SCHEMATIC DIAGRAM OF SURGE GENERATOR AND SURGE-VOLTAGE MEASURING DEVICES

**P. L. Bellaschi:** There is a consensus of opinion expressed in the above discussions to the effect that considerable progress has been made lately in the technique of surge voltage measurement. While it is gratifying to know this, we urge that the profession continue and endeavor to establish the technique of surge voltage measurement on a common and fundamental basis. The following is a resumé and answers the various points brought out in the discussions.

1. *Relationship between Surge Generator Excitation and Surge Voltage Generated.*

Fig. 22 shows schematically the exciting apparatus, the surge generator discharge circuit, and the measuring devices. Control and synchronizing circuits have for simplicity been omitted. The relationship between charging voltage $V$ and the maximum surge voltage generated $E$, for positive and negative polarities, is given in Figs. 23 and 24. These are the curves obtained at the

---

6. "The Theory of Voltage Dividers and Their Use with Cathode Ray Oscillographs," *Bureau of Standards Journal of Research*, July 1932.

Sharon laboratory[7]; the lines are straight and, if projected, intersect the charging volts scale at a point slightly beyond zero. These curves demonstrate that the excitation required for a positive wave voltage is somewhat higher than for the corresponding negative wave voltage. Mr. Clem's conclusion on this matter is in agreement with our results. Consideration of these results and of the surge generator constants obviously lead to another conclusion by Mr. Clem stating that, "After corrections for discharge circuit efficiency have been made, the same impulse generator excitation should be obtained for the short wave as for the long wave."

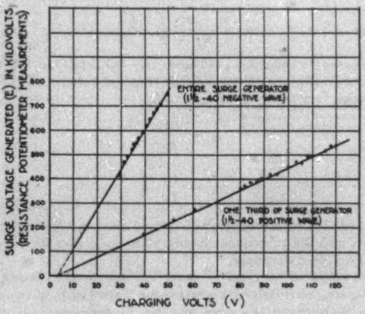

FIG. 23—RELATION BETWEEN CHARGING VOLTS ($V$) AND SURGE VOLTAGE ($E$) APPLIED TO TEST PIECE (TEST BETWEEN ELECTRODES IN OIL)

For a given set-up of the surge generator the excitation voltage affords the only means whereby the surge voltage generated can be controlled and adjusted. The relationship between the surge generator excitation and the surge voltage generated may be used as supplementary to the surge voltage recorded by the measuring devices, in so far as it is a question of securing consistent results, but there is no good reason to justify its use as a basis for fundamental measurement.

### *2. Characteristics of Surge Generators—Calculations of Surge Voltage.*

This subject has been considered at length in the foregoing discussion; little more need be added. Calculations of the surge voltage are useful in that they give an intimate understanding of the characteristics of the surge generator discharge circuit and hence give more confidence in the technique of measurement. However, while the calculated surge voltage undoubtedly serves as a useful guide, it is preposterous to expect the calculated results to be an absolute and complete confirmation of the actual surge voltage. It is obvious then that only through a reliable technique of surge voltage measurement can correct results be obtained. Our criticisms of Messrs. Dowell and Foust's paper also hold in similar respects for Mr. Clem's discussion on the subject of calculated surge voltages.

### *3. The Sphere Gap.*

In his discussion Mr. Clem refers to studies made on the 50-cm sphere gap to determine polarity and time lag effects; he states that neither of these effects exists in appreciable amount within the range of surge voltages he has considered. Mr. Lloyd states rather bluntly that "the accuracy of sphere gap in sparking over without appreciable time lag on the crest of either the short or long wave cannot be questioned." Harding and Sprague caution the use of sphere gaps for rapid surge voltage measurements, and suggest means to pre-ionize the air between the gap and thus eliminate possible time lag effect. Furthermore, Messrs. Fielder and McAuley recommend that sphere gaps duly be calibrated for work in surge voltage measurements.

In the paper and in the writer's previous discussion investigations made on the 200-cm and on the 25-cm sphere gaps have been reported. Similarly, the 6.25-cm sphere gap has been calibrated with the resistance potentiometer; its calibration curve follows the A.I.E.E. curve up to approximately 3 cm gap separation but rises well above the A.I.E.E. curve for the wider separations.

Fig. 27 gives the 200-cm sphere gap calibration down to gap separations of several centimeters. It shows that a small difference exists between the surge voltage flashover for positive and negative waves, the positive wave value being less than the negative wave value.

Fig. 25c gives the flashover of the 200-cm sphere gap (aluminum spheres) when the gap is adjusted just to flashover. The gap separation is 30 cm. The full wave of the surge applied is shown in oscillogram Fig. 25B; to obtain this wave the internal resistance $R_s$ in the surge generator was reduced to a minimum, the other surge generator constants being $C_s = 0.024\ \mu f$ and $L_s = 30\ \mu h$. Two conclusions are derived from this oscillogram. First, the sphere gap missed the first crest of the oscillation and flashover took place at the second crest of the oscillation. Second, the resistance potentiometer was located approximately 20 circuit feet in front of the sphere gap, and it therefore recorded a voltage less than the sphere gap flashover voltage by an amount equal to the lead drop. Fig. 25c then shows that a time lag effect exists particularly in the case of certain waves which nevertheless are encountered at times in the laboratory. As pointed out in the paper the time lag effect may occur even in the case of a long, flat wave surge. Fig. 25c confirms emphatically that measurements must be made close adjacent to the test piece, particularly in the case of very fast surges and when all damping resistance is removed from the surge generator circuit.

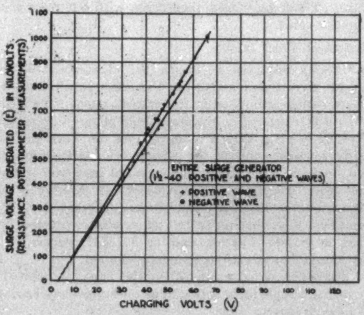

FIG. 24—RELATION BETWEEN CHARGING VOLTS ($V$) AND SURGE VOLTAGE ($E$) APPLIED TO TEST PIECE (TEST BETWEEN ELECTRODES IN OIL)

Referring to Fig. 25D, the internal resistance $R_s$ was increased to 200 ohms and a wave as shown in oscillograms Fig. 26A and B was recorded. The surge voltage was adjusted to a value appreciably above the sphere gap setting (18.75 cm). Flashover took place on the rising front; the voltage as computed from the A.I.E.E. standards is a few per cent within the resistance potentiometer measurement.

---

[7] For discussion of results in another laboratory see also "Technique of Surge Testing," F. D. Fielder, *Electric Journal*, February 1933, p. 73.

Even for waves that are normally or are at times used in the laboratory, it is not justified to state that no time lag effect exists for sphere gaps. Neither can it be said that no polarity effect exists. When flashover takes place on rising fronts in a fraction of a microsecond, the time-lag effect then becomes more prominent.

It cannot be over-emphasized, that the characteristics and the limitations of sphere gaps as used in surge voltage measurements need to be set forth more clearly. Surely present A.I.E.E. calibration curves cannot be used indiscriminately as a standard for surge voltage measurement. Mr. Clem suggests that "the range (of the sphere gap) should be more limited than when used for 60-cycle measurements" and Mr. Peek states that sphere gaps be used up to separations not greater than one-half their diameter. These gentlemen then agree with our recommendations on this point.

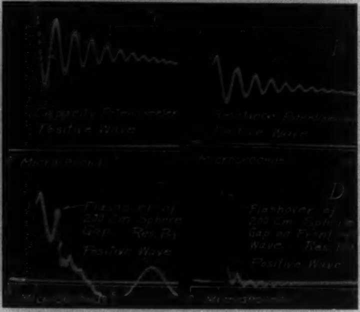

FIG. 25—OSCILLOGRAMS A, B, C AND D

*4. Resistance—Cable Divider.*

Mr. Bewley analyzes at length the characteristics of the cable-type divider and arrives at the same conclusions which either are stated or implied in the writer's paper. This coincidence is to be expected as the theoretical analysis presented by Mr. Bewley is essentially a reiteration of the work the writer originally covered; some of the generalized relationships in the original analysis were not found essential and were therefore omitted from the paper. Nevertheless Mr. Bewley is to be complimented for his analytical work. A great deal of the mathematical relationships he has given also is covered in the work of Heaviside, Carson, and in A.I.E.E. papers,[8] which Bewley himself has at various times contributed.

The derivation of equation (2) in the paper is pointed out briefly and in simple form herewith as questions may have been raised as to its source. Let

$E$ = rectangular surge voltage applied (Fig. 3 of the paper)
$R_0$ = resistance of potentiometer ($R_0$ may be in the order of a thousand times greater than either $Z$ or $R_T$)
$Z$ = surge impedance of cable
$L$ = length of cable
$v$ = velocity of propagation in cable
$R_T$ = terminal resistance

The initial current and voltage waves set up in the cable at time $t = 0$ are

$$i_0 = \frac{E}{R_0 + Z} = \frac{E}{R_0} \text{ (very nearly)}$$

$$e_0 = \frac{EZ}{R_0 + Z} = \frac{EZ}{R_0} \text{ (very nearly)}$$

The current and voltage at the terminal of the cable from time

$$t = \frac{L}{v} \text{ to}$$

$$t = \frac{3L}{v} \text{ are}$$

$$i_T' = \frac{e_T'}{R_T}$$

where
$$e_T' = \frac{2R_T}{R_T + Z} \cdot \frac{EZ}{R_0}$$

By successive reflections between the two ends of the cable that can readily be calculated, the terminal current and voltage approach very nearly the steady values

$$i_T = \frac{E}{R_0}$$

$$e_T = \frac{R_T}{R_0} E$$

The ratio between the terminal voltage upon the first reflection, *i.e.*, $e_T'$ and the subsequent steady value $e_T$ is then as stated in equation (2) of the paper.

The effect of terminal capacity $C_T$ due to the oscillograph plates, etc., obviously is negligible for wave fronts in the order of ½ microsecond and even less, as the time constant of the terminal impedance and the cable surge impedance only is a small fraction of the duration of the steepest front that would at the present be measured. We have covered the subject on the effect of distortion and attenuation at sufficient length. A few hundred feet of cable may be permissible, provided it has the desirable characteristics of practically no distortion, no attenuation, and a practically constant surge impedance.

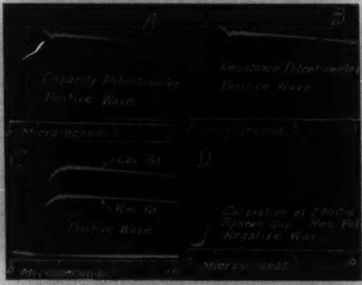

FIG. 26—OSCILLOGRAMS A, B, C AND D

It also is obvious that the inductance of the resistance potentiometer is of secondary importance and that only the distributed capacity need be considered.

Let for example

$R_0$ = 10,000 to 50,000 ohms
$C_g$ = 20 to 100 $\mu\mu f$
$L$ = 10 to 20 $\mu h$,

then obviously the time constant $\frac{R_0 C_g}{4}$ is much greater than

---

[8] See for example: *Traveling-Wave Voltages in Cables*, by H. G. Brinton, F. H. Buller, and W. J. Rudge, TRANS. A.I.E.E., March 1933, p. 121-132.

$L/R_0$. Therefore from a practical standpoint there is no need to consider the inductance of the potentiometer in analyzing the circuit of Fig. 13 of the paper.

The writer's analysis of the characteristics of the resistance potentiometer points out the essential elements of the problem. There are many other practical considerations which invalidate any attempt at too rigorous and detailed analysis. From a practical standpoint we see no need to enter into greater details at the present.

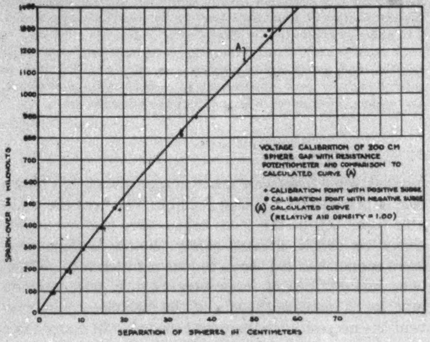

Fig. 27

Mr. Fielder raises the pertinent question as to the values of $R_0$ and $C_g$ which are representative. The values given in Figs. 14 and 15 of the paper are conservatively high but nevertheless representative. These curves can readily be extended to the lower values of $R_0$ and $C_g$ which frequently are found in practise.

Fig. 25A and B compares the response of the resistance potentiometer (approximately 10 ft in length and 10,000 ohms resistance) to that of the capacity potentiometer. The voltages in this case are not measured at exactly the same point in the surge generator discharge circuit, but with the same oscillation superimposed on the exponential component of the wave the pertinent fact is that the surge voltage should rise to crest value at the same time for both the resistance and the capacity potentiometers. This is demonstrated clearly by comparing the time required for the two waves to rise to crest value. Fig. 26A and B is another comparison between the same resistance and capacity potentiometer. Fig. 26C still is another comparison, in this case the wave is of longer duration and is smooth along the front. Mr. Clem should find the above oscillograms of interest as they show that it is possible to use the resistance cable divider as successfully for the short wave as for the long wave.

*5. Capacity Divider.*

Experience with the capacity potentiometer during the past year further substantiates the consistent and satisfactory results that had been obtained previously. The operation of the capacity potentiometer as arranged at the Sharon laboratory meets all practical requirements for the surge testing of transformers. It is gratifying to see that the capacity potentiometer lately has been adopted in other laboratories.[9] The oscillograms in Figs. 25 and 26 and in the paper speak favorably for the capacity potentiometer. Provided the requirements and precautions mentioned in the paper are followed, the objections raised by Mr. Foust and Mr. Lloyd are removed.

The writer prefers the explanation of the theory of the capacity potentiometer as it is given in the paper. The relationships developed in Fig. 16 take care automatically of varying capacity due to space charges, which Mr. Foust mentions. It may be added that the shields have not increased appreciably the capacity of the surge generator at Sharon. The capacity components of the capacity potentiometer in Fig. 18 of the paper are maintained constant by maintaining all metallic parts of the generator, such as static shields, sphere gap, etc., in a given position and also fixing the position of the pick-up elements and of the oscillograph plates.

The following table illustrates the consistent sensitivity of the capacity potentiometer. This particular potentiometer is an adaptation of the one described in the paper and is used to measure surge voltages in the low voltage range from 100 kv to 400 kv.

| | | Resistance potentiometer | | Auxiliary capacity potentiometer | |
|---|---|---|---|---|---|
| Oscillogram No. | Charging volts | Deflection inches | Voltage kv | Deflection inches | Kv per inch |
| A | 75 | 1.58 | †321 | 1.83 | 175 |
| B | 62 | 1.32 | †268 | 1.50 | 178 |
| C | 50 | 1.05 | †213 | 1.20 | 178 |
| D | 36 | 0.76 | †154 | 0.87 | 177 |
| D | 44 | 0.90 | *182 | | |
| E | 44 | | | 1.02 | 178 |

*Multiplier for resistance potentiometer

$$= \frac{10{,}250 + 43.36}{43.36} \times 0.850 = 202 \text{ kv per in.}$$

†Multiplier for resistance potentiometer

$$= \frac{10{,}290 + 43.36}{43.36} \times 0.850 = 203 \text{ kv per in.}$$

# Circuit Breaker Protection for Industrial Circuits

BY H. J. LINGAL* and O. S. JENNINGS†

Non-member Associate, A.I.E.E.

***Synopsis.**—The demand for continuity of service to customers, together with the need to reduce maintenance costs, and increase the safety to operators and property, has made it necessary to improve the protective devices used in the distribution circuit. In the past, this protection has been provided by knife switches and fuses. Limited interrupting capacity of knife switches, together with the possibility of abuse of the fuse, has made it impossible to obtain these desirable characteristics.*

*Increase in design knowledge, the development of new materials, together with an increase in knowledge of arc phenomena, and of arc interrupters has made possible the construction of circuit breakers occupying small space. These same devices are capable of rendering performance superior to that given by older apparatus. At the same time, low cost to the user is obtained, together with safer and more satisfactory service. Safety construction of apparatus, together with tests of unusual severity, assure a product capable of providing a degree of protection to property and life which is considerably more than that obtained from knife switches and fuses, which in many cases can be tampered with and handled while the circuit is alive.*

*The new circuit breakers are suitable for very broad application in all varieties of distribution circuits within the scope of their rating. Standardization of dimensions provides for economical application. The scope of application of these devices is the field now filled by knife switches and fuses, together with many applications in which small oil and carbon circuit breakers are now used. This field in general includes such applications as switchboards, panelboards, load centers, meter entrance equipment, and enclosed switches.*

* * * * *

## HISTORICAL

PROTECTION of circuits from injury or destruction, with the attendant danger to life and property has received continuous attention from engineers and designers all through the history of the distribution of electrical energy for power and illuminating purposes. Protection was necessary in the circuits chiefly to guard against danger created by overloads or unusually heavy current rushes due to short circuits or grounds on the circuit. Of these, the more important was probably the overload, as short circuits, while likely of frequent occurrence, were of small power and could readily be handled by simple devices.

Protective devices then were of the most simple form. The sole object being to open the circuit, if necessary at the expense of destroying the protective device itself, and many times this was accomplished only after considerable damage to property.

The oldest protective device was a section of the circuit which melted when overloads occurred and disconnected the source of power from the point of trouble. Early devices of this type consisted of simple copper wires, or other conductors having a fusing value less than the circuit. These were connected between binding posts or terminals, in air. Evolution in the art finally produced the fuse, and the knife switch which was the only recognized protective device until recently.

Further development, and the necessity for better protection resulted in an enclosed fusible device in which the interrupting capacity was not greatly improved, but a greater safety to apparatus and adjacent property was obtained. Later the fuse cartridge was filled with suitable powders or other materials, still further improving performance.

As the demand for convenience, and protection increased, some fuses were made in such a way that blown elements could be replaced readily. This was the refillable fuse. All of the steps taken were improvements, either to obtain greater safety, better performance, more economical use, or to reduce maintenance. When open installations of fuses were used, it was common practise to increase the size of the fuse element to prevent the necessity for frequent renewals. In many cases circuits were badly overfused and all protection was lost. To obtain increased safety, fuses and suitable disconnecting switches were combined together in a common enclosure, access to which could only be obtained, in many cases, by capable and authorized operators. While safety was materially increased, the element of convenience was lacking.

## DEMAND CREATED FOR IMPROVED PROTECTION

The general speeding up of industry witnessed in the past two decades would not tolerate delay and inconvenience, and has demanded the replacement of any device not able to keep pace, or to meet the new demands made upon it. An open circuit must be reclosed without delay, as soon as the safety to men will permit. Carefully engineered circuit layouts planned to distribute energy at the minimum cost of both distribution and installation require protection that will assist them to perform in the fullest manner the functions for which they were designed. Processes which in their performance, demand continuity of supply, likewise make improved protective devices necessary.

The modern industrial circuit must have dependable protection which cannot readily be tampered with. Careful engineering is wasted and safety sacrificed if someone destroys the value of protection by substitution of protective parts of increased current capacity. The need for better circuit protection has been stressed for many years by fire underwriters and safety councils. Meanwhile the manufacturers of electrical devices have been working to provide better devices.

### REQUIREMENTS

Satisfactory protection carried with it the requirements of:

1. Being able to provide time delay to permit starting of motors, and other operations requiring temporary overload for their performance.
2. Have sufficient interrupting capacity to handle any short circuit likely to occur on the circuit it is protecting.
3. Ability to remove instantaneously a short circuit from the line being protected.
4. Any satisfactory device must be capable of being operated repeatedly in a satisfactory manner, under any condition to which it may be normally subjected.
5. It should be capable of being operated any desired number of times at the will of the operator.
6. It must be built in such a manner that the operator will be safe while operating it.
7. Accessibility and convenience are necessary.
8. The device must not present a fire hazard in any respect.
9. Its performance under unusual duty should not be noisy; or disturbing to the operator or those near it.
10. It must be easy to apply, small in size, and low in cost.

The circuit breaker was the only device available, capable of meeting most of the requirements, but the cost of a breaker of suitable rating and the space required for its mounting prohibited, for many years, the adoption of the device.

### ACCOMPLISHMENTS

Several years ago a small circuit breaker was built, the size of which had been reduced so that in use it occupied about the same space as a switch and fuse of comparable rating. In this circuit breaker there was incorporated a modification of the deion arc interrupter. This breaker had the ability to perform every required function necessary for circuit protection. The first breaker was built in only the 15 amperes 125 volt size and had an interrupting rating of 5,000 amperes. See Fig. 1. Additional ratings have since been developed until now a line is available up to 600 volts and 600 amperes as illustrated in Fig. 2.

Circuit breakers of the conventional type commonly in use extinguished the arc by drawing it to such a length as to cause it to become unstable. Such breakers were not suitable for the protection of branch circuits, because of the space required for their installation. Before a satisfactory circuit protective device could be produced, it was necessary to obtain an interrupting means which would greatly reduce the size of circuit breakers. Dr. Slepian used the theory of deionization to explain circuit interruption,* and suggested a mechanical design of a circuit interrupter which could be adapted to circuit breakers of the type which interrupt the circuit in air. O. S. Jennings at the same time was developing the slotted plate extinguisher, for safety switches, which he applied to these circuit breakers with perfect success. By the aid of the principles which Dr. Slepian had proposed, these extinguishers were finally improved to provide safe interruption at voltages up to 600 volts. The interrupter shown on the breaker in Fig. 4 was the first form used on the Jennings switch referred to. This interrupter requires two plates for each 125 volts of line voltage to be opened. For example, one suitable for opening 250 volts would require 4 plates. As the voltage increases, two plates are added for each 125 volt increase. This interrupter consists of the arc drawing contacts shown at (*B*) in the same figure and the quencher of two or more steel plates (*O*). Upon parting the contacts (*B*), the arc drawn is acted upon by two forces, first, the dense magnetic field produced in the angle created by the contacts and the arc tends to push it off of the contacts and into the slotted portion of the plates. In the slotted portion of the plates a magnetic field about the arc and through the plates exerts a force which pulls the arc to the magnetic center of the plates, at which point it stops moving until, at the end of the next current zero, when current has ceased to flow, the rapid deionization of a cathode layer on the plate surfaces prevents restriking of the arc, and the circuit is interrupted.

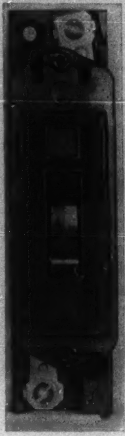

FIG. 1—15-AMP, 125-VOLT, SINGLE POLE CIRCUIT BREAKER

For the higher voltages, and higher interrupting capacities, more effective interrupting is obtained by the use of a deionizing quencher in which the long arc is divided into a number of short arcs, and is made to travel continuously in an annular path instead of stopping as described in the case of the quencher for lower voltage breakers.

The interrupter for higher voltage breakers is illustrated in Fig. 3, and is constructed in the following manner:

---

*Extinction of an A-C Arc*, by J. Slepian, A.I.E.E. TRANS., Vol. 47, 1928, p. 1398.

An extended portion of the main stationary contact is used, upon which to build the quencher, which is constructed in the following manner. An arcing contact member designed to receive one terminal of the arc, and so shaped that the current in passing through it produces a flux in the correct direction to increase the strength of the magnetic field, which drives the arc to the narrow end of the tapered entrance to the plates, is mounted on the main contact member and insulated from it. Upon this member and insulated from it, and from each other, are mounted four copper plates, each of which is set into a steel plate. Next, a five turn coil, the terminals of which are fastened to two plates, one of which is assembled on either side of the coil and insulated from the plates adjacent to it and from the turns of the coil. On the top of the coil assembly there is assembled three more combination plates, and a cover plate. Between each plate and the one next to it an annular raceway is formed by the plates and insulating members. The top plate of the whole assembly referred to as the cover plate, is electrically connected to the moving contact through a shunting member. A hollow steel stud solidly connected to the extended portion of the main stationary contact projects through, and is insulated from the plates and coil. This serves the triple purpose of holding the entire assembly together; providing a portion of the magnetic circuit for the coil which produces the flux which drives the arc on the annular portion of the plates. Being hollow, it also provides for the passage of a screw which is used to secure the quencher to the breaker frame, and at the same time acts as a portion of the conductor to carry the current during the period of arcing from the arcing tip back to the breaker terminal. The circular raceway on the copper plates is obtained by cutting out the center of the insulating material, used between the plates, to the size and shape of the raceway desired, thus permitting the arc to extend from plate to plate. Copper is used in the plates on which the arc is carried, because an arc will move freely over the surface of a copper plate, whereas, it lags, or refuses to move on most other materials. The action of the magnetic field set up by the arc in conjunction with the roughly U-shaped steel plates is used to move the arc from the contacts into the quencher, and on to the copper plates, where it is broken into a number of short arcs. At this point the arc comes under the influence of a magnetic field produced by the coil, which is located in the center of the plate structure.

FIG. 2—600-AMP, 600-VOLT, 3 POLE CIRCUIT BREAKER

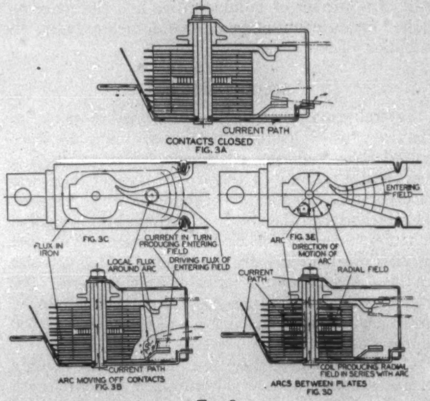

FIG. 3

*A* Interrupter—showing path of current—breaker closed
*B* Interrupter—showing path of current as contacts part
*C* Interrupter—showing flux fields produced by the current in the arc, and conductors, as the contacts part
*D* Interrupter—showing path of current, and flux field when arcs have been transferred to deion plates
*E* Interrupter—showing flux field causing arc to move on plates

Actuated by this field, the arc is caused to travel about the annular path at a high speed (1,100 ft or more per second).

Referring to Fig. 3A, the breaker contacts are shown in the closed position, and the path of the current is then through the extended portion of the main stationary contact, and the contacts themselves as shown by the arrows. In Fig. 3B, the contacts are shown open with an arc drawn between them. The path through which the current flows is now, from the terminal end of the stationary part of the main contact, to the stud in the center of the stack, then through an extension of the arcing tip member, the arcing tip, then through the arc to the moving contact member. Fig. 3B illustrates the flux field produced by the current during a moment when the current is flowing through the portion of the circuit and the arc is shown at Fig. 3A. The local flux around the arc, the flux in the iron plates, and the flux from the current in the turn producing the entering field, all combine to force the arc to travel at high speed to the end of the tapered entrance where it ceases to exist as one long arc, by being broken into a number of short arcs as shown in Fig. 3D. At this time the coil which produces the radial field is inserted into the circuit in series with the short arcs. The flux field produced by the radial field coil is shown in Figs 3D and 3E. This flux acting with the flux in the field produced by the short arcs, will cause the arcs to move in the direction shown in Fig. 3E, thus producing the motion and speed necessary to prevent formation of molten spots or hot cathodes on the copper plates. If the time selected for consideration of the current path, and fields produced, should have been one-half cycle earlier, or later, the direction in which the current is shown to be traveling would be reversed. Likewise, the direction of the flux in all the separate fields would have been opposite to the direction shown. This change in the direction of the current, and the flux fields, would still produce the same direction of motion in the arc, as can be observed by reversing the direction of all the arrows in the illustrations Figs. 3B-3C.

The arc having been broken into a number of short arcs, and caused to move by the means just described, continues to travel in the annular path until a current zero is reached. At this time, if the contacts have separated a sufficient distance to prevent restriking, the arc will be extinguished. In case sufficient separation may not have been obtained between the contacts to prevent restriking through the air, the process of drawing the arc to the end of the tapered entrance, breaking it into short arcs, and moving it around the annular path would be repeated, until the contacts have opened a sufficient distance to prevent restriking.

The selection of materials for contacts was difficult because there had not been sufficient demand to warrant their development up to this time. After much research and testing, it was found that certain mixtures of graphite and silver made a contact member suitable for the lower current breakers as this contact had a low resistance, resisted arcing, and would not weld. This material was suitable for use on breakers normally rated 100 amperes or less. Difficulty was encountered in its use on breakers rated 200 amperes or more, which made it necessary to continue research work still further. The result was the selection of silver and tungsten combinations for breakers rated normally at more than 100 amperes. A further division was necessary because the arcing could not be taken on the main current carrying contacts of the higher current breakers, which made it necessary to separate the arcing portion of the contact from that portion which is intended to carry the normal load. Here again it was necessary to select different materials for the arcing contacts and main contacts. The main contacts required a material having resistance to welding, and low contact resistance at all times. Silver was the best material available, but was unsuitable because of its tendency to weld when carrying heavy current. To overcome this fault, a combination was developed in which the material was silver mixed with tungsten, molded under heat and pressure.

For the arcing contact parts another combination of the same materials was used in which the percentages of the different materials was changed to increase the tungsten and decrease the silver content, which, while it lowered the ability of the contact to carry current continuously, greatly increased its capacity to withstand the destructive action of the arc.

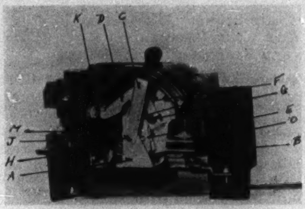

FIG. 4—SECTION THROUGH 15-AMP, 125-VOLT BREAKER SHOWING DETAILS OF CONTACTS AND MECHANISMS*

| | | | |
|---|---|---|---|
| *A* | Frame | *G* | Fulcrum for latching cradle |
| *B* | Contact bar | *H* | Fulcrum for contact bar |
| *C* | Operating handle | *J* | Fulcrum for operating handle |
| *D* | Latching cradle | *K* | Latch |
| *E* | Toggle linkage | *M* | Bi-metal |
| *F* | Operating springs | | |

Operating mechanisms commonly used for operating breakers did not possess all of the requirements needed, and a new design was brought out which was trip-free of the closing handle in all positions when the trip mechanism was actuated. It also was quick-make and quick-break, and held the contacts in the closed position by means of an over-center toggle, which is broken by changing the position of the fulcrum point on the latching cradle when the trip latch is released. The mechanisms used on all breakers are built to incorporate the same general principles although it is necessary to make structural changes in size and shape of the parts to make them suitable for the different sizes of breakers on which they are used. Fig. 4 shows a 15-ampere breaker in which the case has been cut away, to permit a view of the mechanism which, while of the smallest size, is typical of the mechanisms for the entire line. The mechanism is assembled from and consists of the parts as shown in the illustration.

The frame member (*A*) is designed to provide the necessary bearings and fulcrums essential to the operation of the mechanism. On this member is fulcrumed at (*H*) the contact bar (*B*). The contact bar is operated through its travel by means of the toggle links (*E*) which are fulcrumed at one end on the contact bar and on the other end to the latching cradle (*D*). The latching cradle (*D*) is fulcrumed on the frame at (*G*) and latched on the bi-metal at (*K*). Operating springs (*F*) have one end secured to the hinge pin of toggle links (*e*) and the other end to the operating handle (*C*). Assuming the breaker to be in the open position and the latch at (*K*) disengaged, the operations to reclose the breaker are as follows:

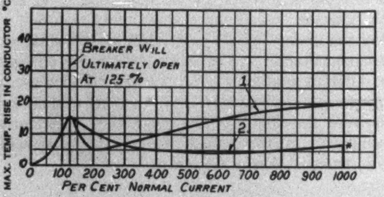

FIG. 5—CURVE SHOWING TEMPERATURE RISE ON RUBBER-COVERED WIRE WHEN CARRYING ITS RATED CURRENT, AND PROTECTED BY A BREAKER OF PROPER RATING

1. No. 14 rubber-covered wire protected by a 15-ampere *AB* deion circuit breaker
2. 220,000-cir mil, rubber-covered cable protected by a 225-ampere *AB* deion circuit breaker

* At 1,000 per cent and above, the 225-ampere breaker trips instantaneously

The operating handle is moved toward the bi-metal forcing the end of the latching cradle into engagement with the latch member on the bi-metal at (*K*). The mechanism is then in the reset position and ready to reclose the breaker. Pushing the operating handle (*C*) toward the contact end of the breaker increases the tension on the springs (*F*) and when movement continues further the direction of the pull on the toggle links is moved from one side of the center line of the upper link to the other side of the same center line. The pull of the springs then cause the toggle linkage to move to the opposite side of the center line of the on toggle position. In doing so, the contact bar is moved at high speed from the open to the closed position and locked against opening by means of the over-center toggle. To open the breaker manually the operating handle is pulled downward, toward the latch, and until the direction of pull of the operating springs, one end of which is moving with the handle, has been transferred to the opposite side of the toggle center when the springs being under considerable tension pull the toggle over center in the direction to open the contacts. Since the springs are under full tension at this time, the movement of the toggle linkage and the contacts will be very rapid. In opening automatically, the latched end of the latching cradle (*D*) is released at (*K*) by the movement of the bi-metal (*M*) which on the breaker shown carries all the current passing through the breaker and is caused to deflect away, from the latching cradle, by the heat generated in it. The latching cradle upon being released moves upward and shifts the upper fulcrum point of the toggle linkage to a point on the opposite side of the line of pull of the operating springs, whereupon the toggle is free to move to the collapsed position carrying with it the contact bar to the full open position.

The complete line of breakers are tripped automatically on overloads by means of bi-metal tripping elements which provide inverse time delay tripping because of their thermal characteristics. The bi-metals used on breakers rated normally at 100 amperes or less are heated directly by the passage of current through them. Bi-metals on breakers rated more than 100 amperes do not carry the current, but are heated indirectly by means of heaters, which are in series with and form a part of the conductor through the breaker. Breakers rated 70 amperes or more are also provided with a solenoid trip operated by a one-turn series coil. These trips are normally set to function at about ten times the normal rating of the trip element, and having no time delay enable the breakers to clear a line in case of a short circuit in a very short time.

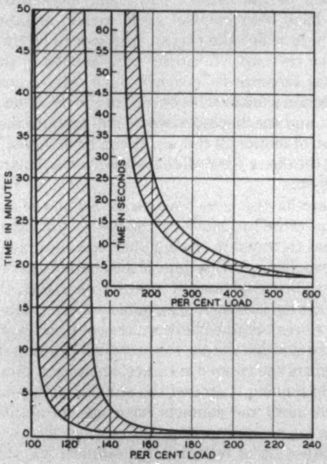

FIG. 6—BAND CURVE, 15-AMP TO 25-AMP BREAKER

Breakers rated at less than 70 amperes do not have the instantaneous trip. In such cases the series bi-metal is heated directly by the passage of current through it and consequently reaches a temperature which will produce sufficient deflection to cause tripping in less than one-eighth of a cycle of 60-cycle current at interrupting rating.

Tripping elements are built integral with, and calibrated in the breakers for rating less than 70 amperes, but for breakers of larger current rating they are built as a unit, calibrated, and sealed, and are interchangeable. Likewise, it is possible to equip any breaker normally rated 70 amperes or more with trips having a normal current rating of 50 amperes or more up to the rating of the breaker. In order to meet requirements of the underwriters, all tripping elements are sealed to prevent tampering or changing of their calibration by unauthorized persons.

The bi-metals are designed with a time current curve that always will protect the conductors of a circuit on which they are used, if correctly applied.

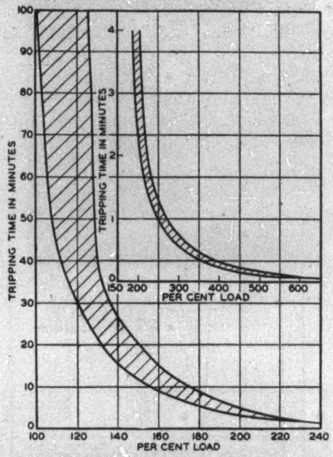

FIG. 7—BAND CURVE, 225-AMP BREAKER

The curve shown in Fig. 5 shows the temperature rise in No. 14 rubber covered wire when protected by a 15-ampere deion circuit breaker and a 200,000-cir mil cable protected by a 225-ampere breaker. At 125 per cent load the wire temperature rises about 16 deg C and the breaker opens ultimately, while at 30 amperes the rise is but 5 deg C and the opening time is 20 seconds. At 150 amperes the temperature rise is 20 deg C and the opening time of the breaker is one second, for the 15-ampere breaker. The curve for the 200,000-cir mil cable shows slightly different characteristics, as the temperature at the higher current is less than for the smaller wire.

Figs. 6 and 7 show characteristic band curves illustrating the performance of breakers rated from 15 amperes to 225 amperes inclusive.

The Underwriters' Laboratories requirements under which the type "AB" circuit breakers are listed, are as follows:

1. *Non-tamperable.*
2. *Trip free of handle.*
3. Unless rated alternating current, only, all tests to be made on direct current.
4. *Overload test.*
   50 operations at 150 per cent load.
   15 operations at 1,000 per cent load.
5. *Endurance test.*
   6,000 operations at 100 per cent load.
   Not over 6 operations per minute.
6. *Calibration test at 24 deg cent*
   0—30-ampere ratings must trip in 1 minute at 200 per cent load.
   31—60-ampere ratings must trip in 2 minutes at 200 per cent load.
   61—100-ampere ratings must trip in 4 minutes at 200 per cent load.
   101—225-ampere ratings must trip in 8 minutes at 200 per cent load.
   226—400-ampere ratings must trip in 15 minutes at 200 per cent load.
   401—600-ampere ratings must trip in 20 minutes at 200 per cent load.
7. Ultimate trip 125 per cent load.
8. Carry continuously 100 per cent load.
9. *Temperature test.*
   Current carrying parts, except thermal elements, must not exceed 30 deg cent rise when carrying rated current at rated frequency. The thermal elements of breakers rated at 225 amperes and above are replaced with copper bars when this test is made, as in the case of safety switches.
10. *Short-circuit tests.*
    A d-c rated circuit breaker must be short-circuited three times at two-minute intervals at rated voltage on a circuit set to give a line drop equal to 2 per cent of the rated voltage with rated current flowing, except the short-circuit current must not be less than 5,000 amperes and not more than 10,000 amperes.
    An a-c rated circuit breaker must be short-circuited seven times at two-minute intervals at rated voltage and rated frequency (60 cycles if none is specified) and 40 to 50 per cent power factor on a circuit set as above for d-c breaker. One three-phase short circuit and six single-phase short circuits are made all at not less than two-minute intervals. Of the single-phase short circuits, two are made on each pole, one *OCO* and one *CO*. The circuit is set as above for the three-phase short circuit and this same circuit is used for single-phase short circuit.
11. Check breaker tripping at 200 per cent load.
12. *Insulation test.*
    1,000 volts plus twice rated voltage between live parts and ground—opposite polarities—line and load contacts with breaker open.

Oscillogram A illustrates the performance of a 225-ampere breaker opening 10,000 amperes at 580 volts alternating current, 60 cycles, 40 per cent power factor.

The diagram in Fig. 8 serves to illustrate typical locations where breakers are suitable for use. At the extreme lower left the service enters a building. Beyond this point the main feeder is protected by a breaker at the service. From this main are taken various feeders. The first on the left is one for elevators, the motors for which may be located, for example, in a penthouse at the top of the building. The circuit for each elevator is in turn protected by a breaker.

Next is a feeder for a power panel, located on one of the upper floors. The next circuit shown is a lighting feeder which would serve the lighting panelboards for the building, or a section of the building. The last is a power feeder from which has been tapped a sub-feeder protected by a circuit breaker. From this sub-feeder are taken the various motor circuits.

The breakers shown at the main might be individual breakers in boxes, in the form of a switchboard, or in panelboard form, depending on the number of circuits and the nature of the building. The grouping of motor circuits might be accomplished in any one of these ways. Since the breaker mechanisms are all identical, the same performance would be obtained no matter what form the housing takes. Fig. 9 has been selected to illustrate some applications of the breakers to motor circuits. In this illustration, circuit No. 5 is one frequently found in practise. Immediately ahead of the motor is a motor starter with overload protection. The function of the starter is to operate the motor and protect its coils. Normally the protection afforded by the starter would protect the motor from excessive overloads whose value does not rise above the locked rotor current.

Oscillogram A

The overcurrent device in the starter is designed to act with greater time lag than the circuit breaker, but in securing this lag the ability of the starter to interrupt current is reduced to approximately the locked rotor current of the motor. In the illustration, a breaker is placed immediately ahead of the starter. The function of the breaker in this case is to disconnect the starter and motor from the line, and to protect the starter, and motor from currents greater than the capacity of the starter to interrupt. In order that the time lag in the breaker will be sufficient to permit the starter to function on overloads within its rating, the trip element in the breaker is selected so that it will operate faster than the starter at about locked rotor current. It is obvious from the position of the starter, that it cannot give protection to anything but the motor itself, while the circuit breaker located at the source of the circuit affords protection for the entire circuit, starter, and motor.

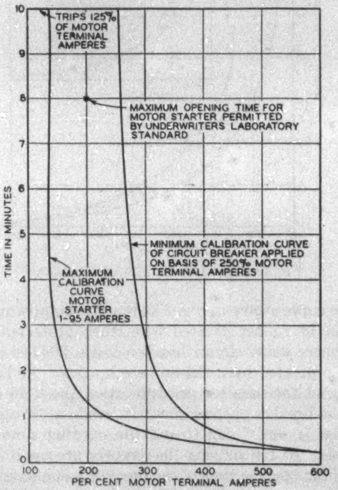

Fig. 10—Comparison of Motor Starter Curve and Circuit Breaker Curve

Circuit No. 4 shows the motor very close to the circuit breaker. In this case the switching function of the breaker may be utilized to omit the motor circuit switch. Circuit No. 3 shows a group of motors of the same size. If desired, one motor circuit switch may serve to disconnect all the motors. Circuit No. 2 is essentially the same type except that one motor has the capacity of more than 40 per cent of the total. Circuit No. 1 serves to illustrate a circuit in which it is not desirable to depend on the breaker at the origin of the feeder for protection, because a short circuit at any one of the motors would interrupt the operation of the others; for this reason a circuit breaker is placed on each separate motor circuit, even though conditions do not require such protection from a safety standpoint. If these are short taps, the motor circuit switch may be omitted.

FIG. 12—ONE FORM OF DISTRIBUTION SWITCHBOARD ACCESSIBLE FROM THE FRONT FOR INSPECTION

At the present stage of development, the circuit breakers do not serve all of the purposes of a motor starter, and it is essential in many cases to use both the breaker and starter. In some cases, however, the breakers will perform all of the functions required, giving the required protection to both the motor and circuit.

FIG. 13—A METHOD OF MOUNTING WHICH EFFECTS A HIGH DEGREE OF SAFETY

The curves in Fig. 10 show the difference in shape between a typical motor starter and a typical *AB* deion circuit breaker. The motor starter curve is plotted to show a tripping at 125 per cent of terminal ampere rating of a motor. The circuit breaker is plotted to carry 250 per cent of the motor full-load current. It is to be noted that the curves of the breaker and the starter cross about locked rotor current. As just described, due to the conditions surrounding a motor circuit, it is not desirable to have the circuit breaker trip below the pull-out load of the motor.

The small circle between the two curves represents the point established by the Underwriters' Laboratories as the maximum permissible time at which a motor starter shall trip at 200 per cent load,* which is, as previously stated, under the Underwriters' Laboratories standard for circuit breakers.†

If the circuit breaker curve were plotted to start at a lower ratio to the motor starter, it would cross the motor starter curve at correspondingly lower overload. If this ratio were still further reduced, it would be possible to reach a condition where, in ordinary plant operation, the breaker would trip before the starter.

The difference in the shape of the two curves in Fig. 10 is necessary because of the difference in the heating characteristics of motor windings and rubber-covered wire. As the size of rubber-covered wire increases, it more closely approaches the motor in thermal overload characteristics, permitting a decrease in the ratio of sizes. The National Electric Code‡ states that motor circuit overcurrent protection shall have a continuous current carrying capacity of at least 115 per cent and never more than 250 per cent in the case of time limit circuit breakers applied to motors of not over 30 amperes. At about 30 amperes 20 per cent only is allowed.

The design of all sizes of breakers has been carefully worked out to permit economical assembly, interchangeability, and convertibility. It is possible to use the breakers either singly, or to bank them in groups as shown in Fig. 11, which illustrates a lighting panel in which breakers ranging in size from 15 amperes to 600 amperes can be assembled. In such an assembly breakers rated 50 amperes or less occupy one-fourth the space of a 225-ampere, or 600-ampere breaker. Breakers rated at 100 amperes occupy one-half the space of a 225-ampere, or 600-ampere breaker. In all cases it is assumed that the breakers are of a like number of poles. It is possible to remove the two 100-ampere breakers from the assembly shown in Fig. 11, and replace them with a 225-ampere, or 600-ampere breaker. Likewise, 12-single pole, 15-ampere breakers may be removed and be replaced in the same space with one 600-ampere breaker, or one 225-ampere breaker.

It is not always desirable to use the type of construction shown in Fig. 11. The breakers are suitable for many other types of installation, and Fig. 12 illustrates a representative form of distribution switchboard accessible from the front for inspection.

Another form of construction adaptable to the economic grouping of breakers for power panels or switchboards is shown in Fig. 13. This method is more expensive than the method referred to in the previous paragraph, but provides greater accessibility, and at the same time enables the circuit breaker to be completely disconnected from the bus.

## Discussion

**R. E. Hellmund:** The desirability of replacing fuses and knife switches by suitable breakers has been pointed out in the paper and it is so obvious that it may cause wonder why it has not been done long ago. However, a study of the paper reveals that a great many engineering and research problems had to be solved before a suitable device was even possible. It is not obviously an easy problem to condense into a few cubic inches, an operating mechanism having quick make and break features for automatic or hand operation, trip free of the handle, a tripping mechanism with thermal features, contacts, and arcing space, all sufficiently large to handle 5,000 to 10,000 amp. Besides working out the structural design features, it required research and development on new arc rupturing methods and principles, new contact materials, new materials for the thermal elements, etc. These factors which are mentioned in the paper represent however, only a part of the problem. The testing with large rupturing currents in line with the underwriters' laboratories requirements, which for obviously practical reasons are and must be limited in number, had to be supplemented by numerous other tests. These included tests to determine the adequacy of the breakers on both direct current and alternating current, with various combinations of circuit constants such as resistance and inductance; with variations in damping effects in the circuit devices; with different locations of the impedances ahead or behind the breakers; with different grounding conditions and with different values of many other variables. It is true enough that the same variations were in the past encountered with fuse protection but the fuse had the advantage of gradual development and accumulation of experience with the growth of the electrical industry as a whole, while these breakers must at once meet the varied requirements of a fully established industry. Also as compared with a single operation of a fuse, many repeated operations, with a maintenance of operable conditions, are required of the breakers.

However, there is one more rupturing problem encountered with circuit breakers, the importance of which is not generally appreciated. A fuse is never called upon to rupture currents below those which cause it to melt. With a breaker permitting hand operation, an ability for handling these smaller currents is of course required. With open breakers and knife switches permitting wide separation of contacts these smaller currents present no difficulty. However, with the space limitations of these inclosed breakers, special provisions and features are required to take care of them and under certain conditions the problem fully is as difficult as that encountered with the maximum rupturing currents. Literally hundreds of thousand of tests were made to check all these conditions and assure coverage of probably 99.9 per cent of the possibilities which may be encountered in practise.

Even with all this, cases can be imagined where a breaker may be used with one of the higher d-c voltages in a circuit with extremely high inductance and no damping effects in the apparatus to be handled (air core inductance) where current rupture will not readily be accomplished. Of course it would be uneconomical to design for such extreme cases representing perhaps 1/100 per cent of the possible applications.

The number of tests and checks which were necessary with regard to the thermal trip elements were of the same order as those in connection with rupturing ability. Besides the features mentioned in the paper the ambient air temperatures had to be studied in combination with the influence of conductors, current carrying joints, other breakers and many other heat generating parts which may be mounted in close proximity to a breaker.

These are but a few of many additional items which add to the extreme complexity of a design problem which on the surface may look comparatively simple.

---

*Refer to Underwriters' Test Procedure E-7819.

†Time established for 200 per cent of circuit breaker rating is 1 min for breakers up to 30 amp, 2 min for 60 amp, 4 min for 100 amp, and 8 min for 200 amp.

# Variable-Voltage Oil Well Drilling Equipment

## Comparison of Characteristics of Various Combinations of Motors and Generators

BY A. H. ALBRECHT*

Member, A.I.E.E.

***Synopsis.**—In the past, there have been many operating data taken and used in the comparison of the characteristics of various types of prime movers. However, there has never been a method established for the comparison of these equipments on a common basis. In this paper, such a method has been proposed. Although it deals only with internal combustion engine direct-current electric drives, with varying electrical characteristics, this method may be advantageously used for the comparison of other types of prime movers.*

VARIABLE-voltage direct-current drives are the most recent advance in electric oil well drilling equipment and have been successfully used by both the cable tool and the rotary method of drilling.

In the case of cable tool drilling, which consists of merely raising and dropping a heavy bit by means of a walking beam, the characteristics of d-c equipment result in improved motion of the drilling tool and in reduction of the time required for withdrawing the tools from the hole.

Rotary drilling, with its greater power requirements and greater complexity of operations, shows a more marked improvement when performed with d-c equipment than does cable tool drilling.

There are two fundamental operations when drilling by the rotary method, namely, the drilling operation and the hoisting operation. When drilling, hole is made by the downward pressure and cutting action of a revolving steel bit. The bit is rotated by means of a long steel pipe, extending from the drilling tool upward to a power driven rotary table mounted over the mouth of the well. Although the table has a positive grip on the drill stem, the latter is free to move vertically through the table while it is in motion.

To the top of the drill stem a swivel is attached, which provides a means of suspending the stem in the well, allowing it to rotate with the table, while the upper part of the swivel, the hoisting block and supporting cable, remain stationary. The drill stem and swivel are hollow so that mud can be pumped down the drill pipe to the drilling bit and out into the well through suitable holes in the bit. This fluid picks up the material loosened by the bit and carries it to the surface through the space between the drill pipe and the walls of the well. This circulation of fluid through the well is maintained by the pressure of two pumps connecting through a flexible hose to the swivel on top of the drill stem.

The swivel, drill stem, and bit may be raised or lowered in the well by means of a steel cable, operating through a hoisting block strung from the sheaves at the crown of the derrick. The free end of this cable passes down the derrick and is wound on a hoisting drum. This drum is a part of the drawworks which serves as a distribution center for all power-driven parts of the rig except the pumps. A system of chains, sprockets, and clutches is so arranged that normally, four-speed ratios may be obtained at the drum.

In order to replace a dulled bit, the entire drill stem must be withdrawn from the hole and is accomplished by removing the drill pipe in approximately 90-foot sections. During this operation, the hoist motor is loaded to its maximum capacity, for it is customary to hoist the drill stem at the greatest practical speed.

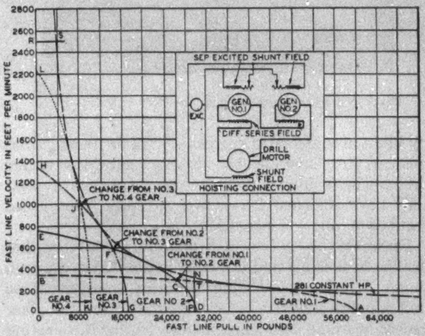

FIG. 1—COMBINATION 1

When returning the drill stem into the well, it is necessary to raise the empty elevators as rapidly as practical.

For performing the complete hoisting cycle in the most satisfactory manner, it is necessary that the hoisting motor be capable of exerting high torque for short periods of time, have a high no-load speed, and be capable of being reversed quickly.

The pumps used for circulating the mud are called upon to operate over a wide range of pressure and volume. In case the bit becomes plugged, it is desirable that the pump stalls at a safe working pressure.

In order to perform all of the pump operations satisfactorily, it is essential for the mud pump motor to have

---

*Standard Oil Co. of California, La Habra, California.

*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

a high no-load speed, a definite limit of maximum torque and, because of the continuity of operation, to operate efficiently at all speeds.

A typical installation of a variable-voltage drilling equipment consists of a power plant (see Fig. 5) located at a safe distance from the drilling rig, and two motors located in the drilling rig.

The power plant consists of two d-c generators with direct-connected exciters. These generators may be driven by an a-c electric motor, taking energy from the usual power supply, or they may be driven by steam or by internal combustion engines. All of the installations made to date have used the internal combustion engine drive. The requirements for the prime movers are that they have sufficient horsepower capacity, good speed regulation, and low operating costs.

Birdseye View of Derrick and Generating Plant

One motor drives the drawworks and is used for either drilling or hoisting and the other motor drives the mud pump. During the drilling operation, one generating unit supplies power to the drilling motor and the other generator to the mud pump motor. During the hoisting operation, however, as the mud pump is not ordinarily used, the power from both generators is supplied to the drilling motor.

In view of the different operating characteristics obtainable by the use of various types of motor and generator windings, and interconnections between machines, an investigation was carried on to determine which combination was best suited for rotary drilling. This study included the following combinations:

1. Differential generators designed for series connection, supplying energy to a shunt drilling motor.
2. Differential generators designed for parallel connection, supplying energy to a shunt drilling motor.
3. Differential generators, designed for series connection, supplying energy to a compound drilling motor.
4. Shunt generators, designed for series connection, supplying energy to a compound drilling motor.

Each of these combinations uses the variable-voltage system of control. When the two generators are connected in series, to supply full power to the drilling motor for hoisting, the drilling motor is operated on double voltage, thereby doubling the motor speed and horse power. However, neither the motor ampere input nor the available motor torque is changed.

When the two generators are connected in parallel to supply the total power to the drilling motor, the voltage applied to the drilling motor remains the same as when one generator is connected to it. However, the available current is approximately doubled, thereby doubling the horse power output of the drilling motor.

Combinations 1, 3 and 4, as listed above, use the series connection of generators and combination 2 uses the parallel connection of supplying maximum power to the drilling motor during hoisting.

## Points of Consideration

In order to make a complete study of the series and parallel connections under discussion, the following points are considered:

1. Suitability of operation.
2. Relative first cost and operating charges.
3. Relative installation costs.
4. Relative safety.
5. Choice of size of equipment.
6. Choice of electrical characteristics.

A View of the Generating House

Showing internal combustion engines, direct-current generators and exciters

Since this is a comparison of electrical equipment and schemes of arranging electrical equipment, the drawworks efficiencies are considered to be one hundred per cent. The excitation is considered constant in all combinations.

*1. Suitability of Operation.*

*Parallel Connection.* It is necessary to use differential compound generators for parallel operation in oil well service. These generators have two fields; namely, a separately excited shunt field, and a differential self-excited field. The differential series field opposes the shunt field, thereby causing the generator voltage and consequent motor speed to droop with increase of load. This characteristic permits adjustment of the generator output to a value such that the prime mover cannot be stalled during normal engine operation, consequently preventing the overloading of the prime mover.

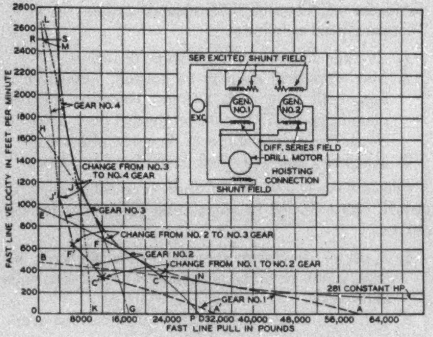

FIG. 2—COMBINATION 2

Assume two differential generators are being operated in parallel, driven by separate engines. If, for any reason one engine slows down, the voltage of its generator drops, causing a partial transfer of load to the other generator. This transfer is momentary and when stability is reached, the resultant voltage and kilowatt output of the slower generator is slightly reduced. The division of load on the generators is in proportion to the respective engine horse power output. Any difference in engine speeds causes an unequal division of load current between the generators, the machine running at the higher speed supplying the larger part of the current.

*Series Connection.* Successful operation of duplicate d-c generators in series is attained with either shunt-wound or differentially compound-wound types of generators.

If duplicate d-c generators are being operated in series and the speed of one engine decreases, the output of its generator decreases in proportion. As the current output is not affected, the available motor torque remains unchanged, but the motor speed is reduced in proportion to the decrease of terminal voltage. Regardless of the condition of operation, there is no transfer of load current between generators. However, both machines can become equally overloaded.

*2. Relative First Cost and Operating Charges.*

The first cost of the series connected and the parallel connected combinations should be practically the same. Experience has shown that if the equipments are properly designed for their operating voltages there will be no appreciable difference in operating cost.

*3. Relative Installation Cost.*

The only difference in the installation costs of either of the four combinations is in the wiring. Because the current is doubled when hoisting with the parallel-connected equipment, the wire to the drilling motor must be approximately double in size to that used for series-connected equipment, for the same voltage drop.

*4. Relative Safety.*

From a safety standpoint, there is very little advantage to be gained by the choice of either equipment. In both cases, the combined no-load voltage of either the hoisting or drilling connection is below 600 volts. As rubber covered wire used in these installations is rated at 600 volts with a safety factor of five, and as all live parts are normally protected, both connections are equally safe. In case of trouble the plant operator and not the drilling crew makes the necessary repairs.

As a specific example of voltage values of generators operating in series and in parallel the following may be considered. The combined no-load voltage of two generators in the series combination is approximately 580 volts. The no-load voltage of generators in the parallel-connection equipment is approximately 450 volts. The full-load voltage of the generators in each combination is 250 volts. If two generators designed for parallel operation were connected in series, the combined voltage would be unsafe but when the generators are designed for a particular connection, the combined no-load voltage of either connection is below 600 volts.

VIEW OF DERRICK FLOOR

Showing rotary table with upper end of dull stem, also front view of drawworks with driller, on the extreme left. The other four men are members of the rotary crew

*5. Choice of Size of Equipment.*

A comparison of characteristics might be made of equipment having any assumed value of horse power. In the comparison made here a power plant equipment consisting of two 200 hp engines driving 125-kw generators is chosen because this capacity is considered sufficient for present-day drilling.

The drilling motor, taking power from both engine-driven generating units when hoisting, should be designed to have a maximum output of 281 hp. This value represents the combined engine ratings less losses and auxiliary power. It is essential that the characteristics of the drilling motor and the generators be such that the prime mover will operate at its maximum output over the widest possible range of torque and speed.

Control Cabinet Located in Generator House Showing Meters and Auxiliary Switches

The horse power ratings of electrical equipment are the same for either of the combinations being considered; however, the electrical characteristics are widely different.

*6. Choice of Electrical Characteristics.*

*General.* One of the most important duties of any type or kind of equipment used for drilling oil wells is to hoist strings of drill pipe. It is, therefore, reasonable to assume that the best combination of generator and motor characteristics for such work is that in which the engines driving the generators will be loaded to their normal capacity for the maximum time of the hoisting cycle.

In order to make a true comparison of the characteristics of these various equipments and eliminate differences in types and ratings, their speed-torque characteristics are converted into fast-line speed and fast-line pull, (the fast line being the one wound directly on the hoisting drum) using the most advantageous drawworks sprocket ratios in each case. Plotting these values in the form of curves, together with a curve representing the net available constant engine output, results in a visual picture of the behavior of each equipment.

In order to convert these values to get fast-line speed and fast-line pull, it was necessary to assume average values for weights and dimensions of various rig parts. These are listed as follows:

1. Average diameter of hoist drum, 30 inches.
2. Maximum drill stem to be hoisted, 7,500 feet of 6-in. drill pipe with 8 lines, weighing 235,000 pounds, or 29,375 pounds on the fast line. This includes the weight of blocks, line, elevators, etc.
3. Maximum fast-line speed, 2,500 feet per minute.

*Calculations of Data for Curves.* The following procedure was followed in calculating the values for the curves.

1. A set of drawwork sprocket ratios is chosen by trial, which gives the best balance of fast-line pulls and speeds.
2. For each drum speed or gear ratio, various available fast-line speeds are assumed and converted into motor speeds.
3. The motor speeds are used to obtain the corresponding motor torques. These are taken from curves showing the speed and torque of the motors operating on the voltage of the generator used in the combination of equipment considered in each particular case.

Mud Pump and Mud Pump Motor

4. The pull, in pounds, for each fast-line speed is calculated.
5. The fast-line velocity-pull curves are then plotted, using the fast-line speed in (2) as ordinates and the pounds pull in (4) as abscissas.

The fast-line velocity-pull characteristics are calculated for each of the following combinations and the results plotted in the form of curves as designated.

TABLE I

| Combination | Type of generators | Generator connection | Type of motor | Fig. No. |
|---|---|---|---|---|
| No. 1 | Differential | Series | Shunt | 1 |
| No. 2 | Differential | Parallel | Shunt | 2 |
| No. 3 | Differential | Series | Compound | 3 |
| No. 4 | Shunt | Series | Compound | 4 |

## DERIVATION OF ELECTRIC MOTOR CHARACTERISTICS

The speed-torque characteristics of the No. 2 combination and the No. 3 combination were obtained from electrical manufacturers. The curves of the other two combinations were recalculated from manufacturers' curves of different ratings. These estimates are very close, however, and will not make an appreciable difference in the accuracy of the results.

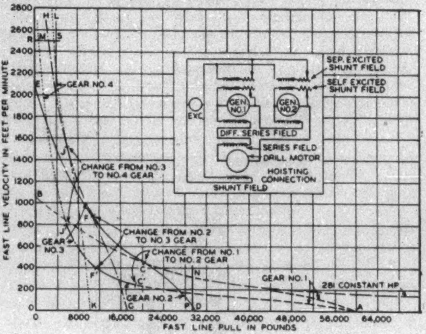

FIG. 3—COMBINATION 3

*Explanation of Curves.* For each of the four combinations a constant horse power curve *NS* (see Figs. 1, 2, 3 and 4) representing the net available constant prime mover output of 281 hp is first drawn, using fast-line speeds as ordinates and fast-line pulls as abscissas. As the product of velocity and pull is proportional to horse power, the area under this curve is proportional to the maximum energy which is expended with this constant output, and represents the characteristics of an ideal equipment having an infinite number of gear ratios. Therefore, since the area *NPORS*, in Figs. 1, 2, 3 and 4, within the limits previous specified, is the maximum obtainable, it will be considered 100 per cent. The velocity-pull characteristics of a four-speed drawworks are then drawn, using gear ratios which utilize the motor characteristics of each combination to the best advantage. In each figure, the characteristics of low-low or No. 1 gear is shown by curve *AB*, high-low or No. 2 gear by curve *DE*, low-high or No. 3 gear by curve *GH* and high-high or No. 4 gear by curve *KL*.

As the areas representing the energy expended by equipments driving four-speed drawworks, do not coincide at all points with the ideal area *NPORS*, the motor characteristics determine how closely it is approached.

In order to obtain maximum energy from any combination, it is necessary to change gears at definite values of fast-line pull as shown by points *C*, *F*, and *J* in Figs. 1, 2, 3 and 4. The energy from any of the combinations is proportional to the area *NPORSJFC* and, compared with the area under the ideal curve *NS*, is as follows for the various combinations:

TABLE II

| Combination | Per cent of area *NPORS* | Fig. No. |
|---|---|---|
| 1 | 91.3 | 1 |
| 2 | 96.1 | 2 |
| 3 | 99.7 | 3 |
| 4 | 99.4 | 4 |

On this basis of comparison, combinations 3 and 4 utilize the engine output to the best advantage.

Under ordinary conditions, it is rather difficult for the driller to know when to change gears, and unless they are shifted at the correct values of pull, hoisting time is lost. This is especially true of combinations 1 and 2 which have the flattest characteristic and show the smallest increase in speed with decrease of load. Combinations 3 and 4, however, have a rapidly rising characteristic and, even if the driller does not change gears at the correct pull, he does not lose much speed over a comparatively wide range of pull.

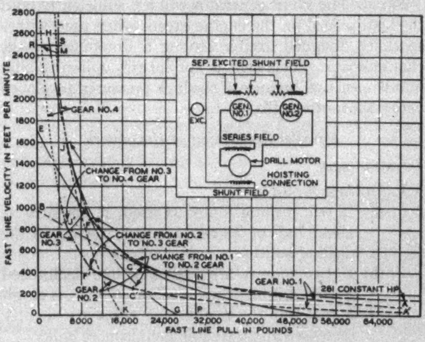

FIG. 4—COMBINATION 4

Another point to be considered is the pull which can be exerted by the various combinations when only one generator is used. It is sufficient to say that, in the series system, the fast-line pull is approximately the same, whether one or two generators are used. However, in the parallel system, the fast-line pull, when one generator is used, is approximately half that available when two generators are used, for the gear ratios selected.

The values of fast-line pull, under the conditions mentioned above, for the various combinations are as follows:

TABLE III

| Combination | Maximum fast-line pull in pounds | | Fig. No. |
|---|---|---|---|
| | One generator | Two generators | |
| No. 1 | 59,800 | 59,800 | 1 |
| No. 2 | 33,000 | 59,800 | 2 |
| No. 3 | 59,800 | 59,800 | 3 |
| No. 4 | 76,200 | 89,500 | 4 |

It is not improbable that one generating unit would be out of service when a full string of drill pipe is in the hole, in which case it would be necessary to increase the number of lines in the blocks if the parallel system as discussed were used, whereas, in the series system, no inconvenience would be caused except a reduction of 50 per cent in the hoisting speed.

## SUMMARY OF RELATIVE MERITS OF VARIOUS COMBINATIONS

### *Type of Generator*

*Differential.* The differential generator limits the load placed on the engine, limits the pull on the drilling line, and also limits the maximum pressure developed by the mud pump.

*Shunt.* The shunt generator will not sufficiently limit the load placed on the engine except when used with a specially designed exciter having a drooping voltage characteristic. This type is not entirely suited to mud pump operation because of the high pressures developed before the motor stalls.

### *Parallel Connection of Generators*

*Disadvantages.*

1. Drilling Motor.
   (a) If one drilling motor is used, it operates at about half of its rated capacity when in the drilling position.
   (b) If two motors are used and one declutched during drilling, the objection in 1 (a) is eliminated, but the installation costs are slightly increased and the equipment is more bulky.
2. The cross section of wire for armature circuits from the generators to the drilling motor must be double the size used in the series system.
3. The fast-line pull available, is reduced approximately 50 per cent when one generator is out of operation.

### *Series Generator Connection*

*Advantages.*

1. Drilling motor operates at its rated torque for either drilling or hoisting. The horse power capacity is doubled for hoisting by increased voltage.
2. Size of wire for armature circuits between generators and motor is one-half that of the parallel connection.
3. The fast-line pull available, is approximately the same with one generator as with two.

### *Type of Motor*

*Shunt.* The shunt-wound motor in itself has the disadvantage of a flat characteristic which gives very little speed variation over its operating range. However, this characteristic is caused to droop by the drooping voltage characteristic of the differential generators.

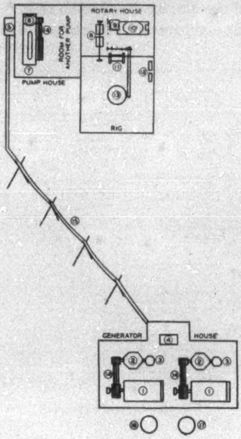

FIG. 5—LAYOUT FOR VARIABLE VOLTAGE OIL WELL DRILLING EQUIPMENT

1. 200 hp internal combustion engine
2. 125-kw d-c generator
3. 15-kw d-c exciter
4. Variable voltage control
5. Terminal box
6. 125-hp d-c mud-pump motor
7. Power-driven mud-pump
8. Master control
9. Reduction gear for drilling motor
10. 125/250-hp d-c drilling motor
11. Drawworks
12. D-c ammeters
13. Rotary table
14. "V" belt drive
15. Wiring between engine house and rig, carried on "X" supports
16. Water tank for engines
17. Fuel tank for engines

*Compound.* The compound motor in itself has the advantage of a steep characteristic which gives wide speed variations over its operating range.

## CONCLUSIONS

An analysis of this paper shows that all four combinations discussed can be used satisfactorily for the drilling of an oil well. However, the "Summary of the Relative Merits of the Various Combinations," shows that each equipment has its distinct advantages. Therefore, an operator should choose that equipment which would give him the best overall results.

## Discussion

**W. G. Taylor:** In his summary of the relative merits of the various combinations, Mr. Albrecht shows that the differential generator is preferable to the shunt generator, a conclusion with which I concur. However, his comparison of parallel with series connections is apparently disassociated from the question of type of generator used, and if this comparison is made with reference to the use of differential generators in each case, the conclusions which will be reached will be quite different.

In making such a comparison, it is necessary to base it on definite motor and generator voltages for each system. In the parallel system, to keep within the maximum voltage of 600 indicated by Mr. Albrecht, a rated voltage of 250 for motors and generators will meet this requirement, as the maximum no-load voltage with one or two generators will be approximately 450. In the series system, Mr. Albrecht states that the combined maximum voltage of two 250-volt differential generators would be unsafe. Furthermore, such a combination would impose a maximum voltage on the draw works motor which would too closely approach the inherent limits of satisfactory commutator design. Therefore, to keep within the indicated maximum of 600 volts requires the use of 125-volt generators and mud pump motors and a 250-volt draw works motor.

Therefore the comparison which follows is based on a parallel system with 250-volt differential generators and motors, and a series system with 125-volt differential generators and mud pump motors and a 250-volt draw works motor.

*Hoisting with Two Generators.* The voltage, current and torque characteristics of both systems will be identical, therefore giving the same performance characteristics in both cases.

The same size of cable will be required between generators and draw works motor in both systems.

*Hoisting with One Generator.* In considering the maximum pull which can be exerted by the various combinations when only one generator is used, Mr. Albrecht intimates that the parallel system has a practical disadvantage, in comparison with the series system, because this maximum pull is only half of that available with two generators or with the series system. He states this disadvantage as a necessity for increasing the number of lines in the blocks to lift a full string of drill pipe in the hole, in case one generating unit of the parallel system is out of service. As a matter of fact, however, this is not necessary under the conditions assumed and illustrated in Mr. Albrecht's discussion or in normal drilling practise generally.

The curves in Fig. 2 illustrate the characteristics of the parallel system applied to conditions in which the maximum weight to be lifted requires a fast-line pull of 29,375 lb. Although Mr. Albrecht has not explained it, curve *J'F'C'A'* represents the hoisting characteristic with only one generator. It will be noted that under this condition it requires a fast-line pull of over 32,000 lb to stall the motor, and the load of 29,375 lb will be lifted, with no increase in the number of lines, at a speed of about 75 or 80 ft per min, which is ample in such an emergency. Not only in this particular case with the parallel system is the available pull sufficient with only one generator, but in the normal application of this system this will be true generally. This is due to the fact that the first or lowest speed of the draw works is too slow over most of its range for regular hoisting service with two generators, and so a variable-voltage equipment would not be selected of such small capacity that it would require a more extended use of the lowest drum speed than that indicated in Fig. 2 to handle the heaviest loads with two generators. This means that an equipment with the parallel system, suitable in capacity to hoist the drill pipe with two generators at the fast speeds demanded by modern drilling practise, will be able to lift the heaviest load with one generator and thus get the drill pipe out of the hole in such an emergency with no increase in the number of lines in the tackle.

*Drilling with One Generator.* In the parallel system, the draw works motor will run under maximum load at full voltage and half of full load current, and at full speed.

In the series system, the draw works motor will run under this same load at half voltage, full current and at half speed. Because of the reduced speed, the self-ventilation will be less effective and the heating consequently higher.

With the same drilling load under consideration for each system, the horsepower demand will be the same in both cases. The parallel system will deliver it at half as much armature and line current as the series system, and therefore with less copper loss and consequently higher efficiency.

*Mud Pump Operation.* In the parallel system, the mud pump motors will have the same rated voltage as the draw works motor, and so they can be and often are duplicates. This makes a mud pump motor available to replace the draw works motor in an emergency if the latter goes out of service.

In the series system, the 125-volt mud pump motor is not a duplicate of the 250-volt draw works motor and so cannot be used in such an emergency, nor will it use the same repair parts. Furthermore the wiring to the 125-volt motor must have twice the current capacity necessary for the corresponding wiring in the parallel system.

*Conclusion.* This definite comparison shows that the parallel system with differential generators is at least equal to the series system in operating characteristics, and is preferable from the standpoint of efficiency, interchangeability, wiring, repairs and application to the standard drilling rig with minimum mechanical changes.

Finally, there is one other practical consideration which I desire to mention as an important influence in the choice of equipments described by Mr. Albrecht, that being with reference to the use of a compound wound motor on the draw works. This motor must be reversed frequently when hoisting drill pipe, and if it is compound wound, suitable control equipment must be furnished to reverse the series field. This adds materially to the first cost, as the currents to be handled are heavy, and it increases the maintenance and departs from the simplicity of the control of the shunt-wound separately excited motor. In view of the comparatively small advantages of a compound winding as outlined by Mr. Albrecht, this complication scarcely seems warranted on a rotary drilling rig.

**A. H. Albrecht:**

1. Mr. Taylor's initial assumption that the comparison of parallel with series connections is disassociated from the type of generator used is in error; Table I of the paper clearly sets forth the type of generators, generator connection, and type of motor for each combination discussed.

2. Mr. Taylor quotes from the paper as follows: "The combined maximum voltage of two 250-volt differential generators would be unsafe." This statement is misleading as he did not complete the sentence. The complete quotation is as follows, "If two generators designed for parallel operation were connected in series, the combined voltage would be unsafe *but* when the generators are designed for a particular connection, the combined no-load voltage of either connection is below 600 volts." The author further states that the full load voltage of the generators in each combination is 250 volts. In other words, two differential generators, each rated 250 volts full load, if properly designed, can be operated in series with a total no-load voltage of less than 600 volts.

3. Mr. Taylor states that, "Therefore, the comparison which follows is based on a parallel system with 250-volt differential generators and motors, and a series system with 125-volt differential generators and mud pump motors and a 250-volt drawworks motor." This comparison also is misleading as the series combinations discussed in the original paper are based on systems utilizing 250-volt generators and a 250/500-volt drawworks

motor. Two of the series systems actually were built and the data used in the paper were based on manufacturer's tests of these equipments.

4. *Hoisting with two generators:* On account of the erroneous assumption discussed above, Mr. Taylor states that the voltage, current, and torque characteristics of both systems will be identical, therefore giving the same performance characteristics in both cases, the same size of cable being required between generators and drawworks motor in both systems. The performance characteristics are not identical but are the same as originally stated by the author. Likewise, the size of cable required for the parallel connection will be twice the size required for the series connection.

5. *Hoisting with one generator:* Mr. Taylor is correct in stating that in Fig. 2, one generator is able to pull the specified weight at about 75 or 80 feet per minute with no increase in the number of lines. However, when the low efficiencies of oil field hoisting equipment and the necessity of meeting such conditions as stuck drill pipe are considered, having maximum pull available at all times is highly desirable.

6. It is true that self-ventilation will be less effective with the series system than with the parallel system when drilling with one generator. However, drilling motors should be provided with forced ventilation for safety so this objection is eliminated.

7. As stated by Mr. Taylor, the mud pump motors, in the parallel system may have the same rating as the drawworks motor which allows interchangeability in case of emergency. However, in practise the mud pump motor requires only about one-half as much horsepower as the drilling motor. Therefore, if these motors are made the same size, the mud pump motors would be larger than necessary or else the drilling motor would be smaller than required.

8. Since the original paper presumed 250-volt mud pump motors in the series system, the wiring and current is the same as for the corresponding parallel system.

9. It seems as though the first paragraph of Mr. Taylor's conclusion is irrevelant since his original assumption is in error. He has not shown in his discussion that either system has any advantage over the other in applying it to the standard drilling rig.

10. In regard to the use of a compound wound motor on the drawworks: If a compound motor were reversed as stated by Mr. Taylor, his arguments would be true. However, it is not necessary to use the compounding in reversing. Consequently, it is necessary only to cut out the series winding by a suitable explosion proof contactor placed on the motor frame and these objections have been eliminated.

To the author's knowledge three wells have been drilled with a compound motor using such a contactor, without experiencing any difficulties. The increase in first cost is negligible. Two additional control wires from the rig controller to the drilling motor, is all that is required over the shunt-wound separately excited motor.

In view of the foregoing discussion, the author feels that the advantages and disadvantages of the parallel and series generator connections as stated in the original paper still hold.

# Recent Developments in Electronic Devices for Industrial Control

BY F. H. GULLIKSEN*

Associate, A.I.E.E.

## INTRODUCTION

SINCE the development of the thermionic amplifier tube, the possibility of using this tube in industrial control equipment has appealed strongly to design engineers. Outside the train control field, however, no serious attempts were made up to a few years ago, actually to install electronic industrial control devices. The reason for this was chiefly that tubes, having sufficient capacity to handle industrial control operations without interposing mechanical relays, were not previously available. With the perfection of the high current, high vacuum tube, with 320 milliamperes capacity, and especially after the development of the grid glow tube with capacity up to 25 amperes, the industrial application of electronic tubes was given added impetus, and during the last few years considerable experimenting has been done to adapt electronic equipment to various industrial control and regulating processes.

At the present time, several successful installations in different branches of industry testify to the superiority of electronic control compared to the conventional electro-mechanical type of equipment. For this reason, the future field for electronic control devices will not only be to perform functions which cannot be accomplished by electro-mechanical or other means; but will also be to supplant electro-mechanical control and regulating devices, especially in applications where high sensitivity and quick response are considered prime requisites.

## GENERAL CHARACTERISTIC OF ELECTRONIC CONTROL DEVICES COMPARED WITH OTHER TYPES OF CONTROL EQUIPMENT

In comparing electronic control equipment with other types of control equipment, several features are readily recognized which make the application of electronic devices desirable from an industrial point of view. The outstanding feature of electronic equipment is the high sensitivity which can be attained without the use of sensitively balanced moving parts. Voltage regulating equipment may be mentioned as an example. Electro-mechanical regulators in most cases need dashpots attached to a sensitively balanced lever system in order to provide damping and to provide the required anti-hunting characteristic. It is obvious that a certain amount of friction will always be present in these dashpots, and the friction may develop to such an extent as to impair the regulator sensitivity unless the dashpot is maintained in proper operating condition. In electronic regulating equipment, as mentioned later in this paper, the anti-hunting function is accomplished by means of a condenser which operates as a friction-free dashpot, and which does not require maintenance.

The absence of moving parts, and consequently, the absence of mechanical inertia, gives electronic equipment an extremely quick response characteristic. This feature is of utmost importance in many industrial control applications where the impulse initiating the control sequence may have a duration of 0.001 second or less. Equipment for control of register in paper cutter applications is a typical example of equipment of this kind.

The absence of mechanical inertia makes electronic equipment ideally suited to applications where the device may be tilted at an angle when operating. A specific example of such installations is the application of voltage regulators on board ship, where minor variations in regulated voltage are liable to occur, when electro-mechanical regulators are used, if the vessel is rolling heavily; while electronic type regulators will not be affected whatsoever.

In several industrial control applications, the controlling force whether mechanical or electrical, may be of such low energy level that its direct application to electro-mechanical control devices will not give the required sensitivity due to the relatively high amount of energy required to operate this type of equipment. Since the energy required to control an electronic amplifier tube may be 1 $\mu$w or less, low energy level control applications can always be worked out satisfactorily by means of electronic equipment. A particular class of low energy level control includes those applications where no contact, either electrical or mechanical can be made with the quantity under control. In that case, practically, the energy level is zero. In such applications positive control can however, frequently be accomplished by means of a light beam, a photocell and associated amplifying equipment. Specific examples of this type of control is outlined later in this paper in connection with alkalinity control and plate glass width control.

Among other desirable features of electronic control equipment may be pointed out the small amount of maintenance required to keep the equipment in proper operating condition. There are no moving parts to be oiled and adjusted for wear, and no contacts to be filed to remove the effect of arcing, as in electro-mechanical control devices. The only maintenance required on a properly designed electronic control device is the replacement of tubes at the end of the useful tube life;

*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

an operation which is accomplished within a few seconds time. Another feature of electronic control which in certain applications may be considered a desirable one is its freedom from noise. In this connection should also be mentioned the absence of radio interference with most types of electronic equipment. A typical example is the electronic voltage regulator for direct current generators, as compared to the vibrating type voltage regulator. The problem of radio interference in connection with direct current control equipment is now being given serious consideration and undoubtedly in the future there will arise occasions where freedom from radio interference will be a point of considerable interest.

Due to the small amount of energy required to control electronic devices, manual control can be accomplished by means of small radio type potentiometers 1½ in. in diameter. This makes it possible to design very compact miniature control panels for various types of process control, and, if desirable the complete control unit may be built into a portable box arranged with a plug for connection to control receptacles located at various strategic points.

There are two other features of electronic type control equipment which must be considered in order to get a true picture of the relative merit of the two types of control. One is the apparent fragility of the electronic tubes, the other is the necessity of occasional tube replacement. Experience with various types of electronic applications indicates however, that the possibility of tube breakage is rather remote provided reasonable care is exercised in handling the tubes. The life of electronic tubes, at rated current, varies between 2,000 and 5,000 operating hours for grid glow tubes, and between 3,500 and 10,000 operating hours for high vacuum tubes. By operating the tubes below the rated current considerably increased life is obtained. As previously mentioned, replacement of tubes can be accomplished within a few seconds time and from a continuity of service point of view, therefore, the necessity of tube replacement is no serious drawback.

In deciding whether to apply electronic control equipment or to apply electro-mechanical or other types of equipment, in a particular installation, the yearly savings due to improved operation should be credited to the electronic side, and the yearly cost of tube replacement should be balanced against the decreased maintenance cost. In many industrial installations it will be found that the cost of tube replacement is insignificant compared to the increased profits due to the higher uniformity of the product, and the consequent decrease in percentage rejections.

## ELECTRONIC TIME DELAY RELAYS

The combination of an electronic tube and a condenser discharge circuit provides the fundamental circuit for a time delay relay which has all the desirable features of the various types of electro-mechanical relays now on the market, and which does not have any of the less desirable features of the electro-mechanical devices.

Electro-mechanical time delay relays may be classified in 5 different groups according to the principle of operation as follows:

1. *Relays With Dashpot*
   - (a) Advantages: Simplicity.
   - (b) Disadvantages: Maximum time delay approximately 10 seconds. The time delay is dependent upon the supply voltage. The time delay is affected by temperature changes due to variations in dashpot damping. Friction may develop in the dashpot with consequent change in time delay. Instantaneous reset cannot be obtained without mechanical complications.
2. *Escapement Relay*
   - (a) Advantages: No temperature error. Instantaneous reset.
   - (b)Disadvantages: The relay is subject to mechanical wear. The relay is noisy. Time delay is limited to approximately 10 seconds.
3. *Motor-Operated Gear Train Relay*
   - (a) Advantages: Time delay adjustable from 30 seconds to 4 minutes.
   - (b) Disadvantages: Expensive. Mechanically complicated.
4. *Flux Decay Type Relays*
   - (a) Advantages: Instantaneous reset. Inexpensive.
   - (b) Disadvantages: Requires direct current for operation. Maximum time delay 8 seconds.
5. *Thermal Relays*
   - (a) Advantages: Inexpensive.
   - (b) Disadvantages: Not very accurate. No instantaneous reset.

The electronic type time delay relay shown in Fig. 1 has all the desirable features of the electro-mechanical type relays previously referred to, and does not have any of the undesirable characteristics.

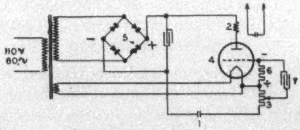

FIG. 1—ELECTRONIC TYPE TIME DELAY RELAY ELEMENTARY DIAGRAM

Referring to Fig. 1, a high vacuum amplifier tube 4 is connected in series with a relay 2 and a potentiometer 3 across the direct current output terminals of rectox 5. When the initiating contacts 1 close, the plate voltage is applied to tube 4, and the current through the coil of relay 2 and through potentiometer 3 starts to build up. The resulting increasing voltage drop across potentiometer 3 will cause a charging current to flow through resistor 6 to condenser 7. This charging current will produce a voltage drop across resistor 6 with a polarity as shown in Fig. 1. This voltage drop will give the grid of tube 4 a negative bias in relation to the cathode of the tube, and for this reason the rate of change of current through tube 4 and consequently, relay 2 will increase slowly. After a predetermined time, dependent upon the adjustment of potentiometer 3, the current through relay 2 will be high enough to operate the relay. The time interval between closure of contacts 1 and operation of relay 2 may be adjusted from zero to maximum by adjusting the movable contact of potentiometer 3 downwards.

The maximum time delay obtainable with the electronic relay is proportional to the product *RC*, where *R* is the resistance of resistor 6 in ohms, and *C* is the capacity of condenser 7 in farads. By adjusting potentiometer 3 any value of time delay between zero and maximum may be obtained. In order to obtain sufficient sensitivity in time delay adjustment, various values of resistor 6 should be used for different time delay ranges. Since resistor 6 is a small grid leak type resistor, the adaptation of the relay to various time delay ranges can be easily accomplished. The maximum time delay of this equipment is approximately 3 minutes and the minimum time delay 0.05 sec. The time delay for any definite adjustment of potentiometer 3 remains constant within ± 5 per cent. The equipment operates from a 110-volt, 60-cycle source, and requires approximately 10 volt-amperes for its operation. The time delay does not vary more than 1 per cent for a-c supply voltage changes within the commercial range of ± 5 per cent.

The electronic type time delay relay is particularly suited to timing applications where frequent adjustment of the time delay is required. A typical application of this nature is in connection with spot welding equipment, where a relay circuit as shown in Fig. 1 meets the desired requirements of accuracy and adjustability.

## Register Control

In various industrial processes it is required to synchronize or register two separate control operations so that space and time relationship between the two remains constant. To illustrate this type of application, the problem of maintaining the register of the knife in paper cutter applications will be outlined. In continuous cutter applications the material to be cut is fed to the cutter from a reel by means of a pair of draw rolls. The cutter is usually of the rotating type and is driven from the same motor as the draw rolls. If there is a printed design on the material, it is desirable to maintain the register of the cut in relation to the printed design. This is obtained by either adjusting the speed of the draw rolls in relation to the cutter speed permanently, or by changing the draw roll speed temporarily. In the latter case the adjustment is equivalent to a space correction of the material to be cut, in relation to the cutter knife.

Present paper cutters require usually three operators for successful operation. One of the operators is kept continuously busy regulating the speed of the draw rolls, another operator stacks the paper when it leaves the cutter, and the third operator sorts the sheets and arranges for further trimming those sheets which have been incorrectly cut. The work of the operator regulating the draw roll speed is exceedingly monotonous, and from time to time he will find the knife cutting the paper considerably off the printed spot used for indicating the proper position of the cut. This results in considerable waste of paper and considerable expense in trimming the sheets to their proper length. By applying photoelectric control of the draw rolls the amount of wasted paper, which at present may be up to 15 per cent or more will be considerably reduced and the number of operators in most cases can be reduced from 3 to 2.

The photoelectric paper register control device operates on the general principle of synchronizing a spot printed on the paper with a pair of cams attached to the rotary cutter shaft. When the cut is in register the contacts operated by the rotating cams do not engage when the photo cell impulse is obtained. For this reason no relay action is obtained. If however, the cut is slightly ahead of the spot or behind the spot one pair of contacts will engage at the instant of photo cell impulse, and by means of suitable amplifying equipment a control relay will be closed and will operate the draw roll speed adjuster or the draw roll position adjuster, in order to bring the paper back in register with the knife.

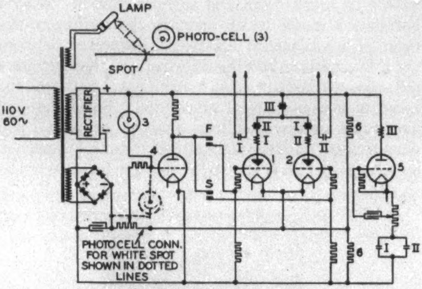

Fig. 2—Elementary Diagram of Electronic Register Control Equipment

In some applications the slip of the paper in relation to the draw rolls is zero or practically constant so that when the speed ratio between the cutter and the draw rolls is once adjusted the entire control can be obtained by means of position control. In other applications the slip varies considerably due to changing paper characteristic, and a speed ratio change as well as a position change is required in order to get satisfactory operation.

In Fig. 2 is shown an elementary diagram of an electronic register control device which will operate either from an impulse received from a white, yellow or red spot on a dark background, or from a dark spot on a white, yellow or red background. The equipment may be arranged for operation with transmitted light when the transparency of the paper is high, or with reflected light when the paper is opaque. A photocell 3 is connected to control the amplifier tube 4 so that when the spot intercepts the beam of light the current through the amplifier tube will decrease. The grid glow tubes 1 and 2 are connected in series with their respective relays I and II, and by means of the voltage divider 6, the grids of tubes 1 and 2 are given a definite negative bias in relation to the cathodes so that tubes 1 and 2 normally will not carry current. Contacts *F* and *S* are operated by the cams connected to the rotating cutter knife, and are adjusted so that the contacts are open when the spot intercepts the light beam if the cutter knife is in register with the design on the paper. If the draw rolls are operating too fast contacts *F* will be closed at the instant of photocell impulse, and consequently, since the current of tube 4 has decreased due to the photocell action, a positive bias will be impressed on the grid of grid glow tube 1, thus causing tube 1 to break down and energize relay I. Relay I energizes a motor which operates the stationary element of a mechanical differential connected between the driving motor and the draw rolls, so that the draw roll speed will be reduced an amount equal to the output speed of the mechanical differential. Since the grid glow tubes are energized from a d-c source, relay I will remain closed until the plate circuit of tube 1 is opened by relay III which is controlled by tube 5 connected in a time delay circuit similar to Fig. 1. If the paper is lagging in relation to the cutter knife contacts *S* will be closed when the photocell impulse occurs and relay II will close to operate the mechanical differential in the reverse direction.

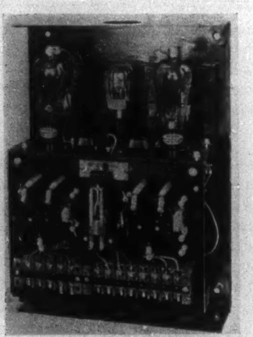

FIG. 3—ELECTRONIC REGISTER CONTROLLER

Due to the application of grid glow tubes the response of this equipment is practically instantaneous so that a sensitivity of 1/16 inch can be obtained with a spot 1/8 inch wide for paper speeds in excess of 500 feet per minute. The equipment operates from a 110-volt, 60-cycle source, and the performance will not be affected by voltage changes within ± 5 per cent. The equipment can be advantageously applied to a variety of cutter installations and its application is not limited to paper cutter applications. A promising field for this type of equipment is the register control of machines for the manufacture of bags of paper, cellophane, cloth or other types of material.

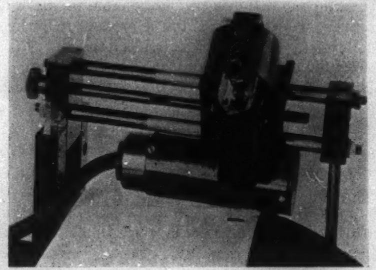

FIG. 4—LIGHT SOURCE AND PHOTO-CELL ASSEMBLY FOR REFLECTED LIGHT APPLICATION

An illustration of the control cabinet is shown in Fig. 3. The light source and photo-cell assembly which is used in reflected-light applications is shown in Fig. 4.

## ELECTRONIC SPEED AND VOLTAGE REGULATORS FOR DIRECT-CURRENT MACHINES

The various electro-mechanical type voltage regulators now on the market have a definite insensitivity zone due to unavoidable friction in dashpots, bearings and other moving parts. By proper design and through careful maintenance the regulator sensitivity however can be kept within a zone of ± 0.5 to 1 per cent which is entirely satisfactory for most industrial applications. In the average industrial regulator application the regulator response is usually not considered to be of much consequence unless lights are connected to the circuits; but there are applications for example in motion picture studios where this feature is of paramount importance. The speed of response of electro-mechanical type voltage regulators is limited by the inertia of levers and other moving parts of the device, and not considering the rheostatic type voltage regulators, the speed of response is also limited by the inherent characteristic of the anti-hunting means.

Anti-hunting is required in any voltage regulating device due to the electrical inertia of the exciter and the generator, and the success of a voltage regulator depends to a large extent upon the proper selection of the anti-hunting means. Through the anti-hunting means a corrective force, either electrical or mechanical, is applied to the primary element of the voltage regulator during the regulating period to counteract the corrective regulator action, so that at all times the rate of voltage correction is proportional to the error in voltage. An electronic type voltage regulator for direct-current generators which meets these requirements of ideal anti-hunting characteristics has recently been developed.

Exhaustive tests seem to prove that in respect to sensitivity and response this regulator is superior to any of the electro-mechanical type voltage regulators previously available.

The schematic diagram of the electronic voltage regulator is shown in Fig. 5. The regulated voltage obtained from potentiometer 5 is bucked against the constant voltage from battery 4, and the voltage difference is applied to the grid of screen grid tube 2.

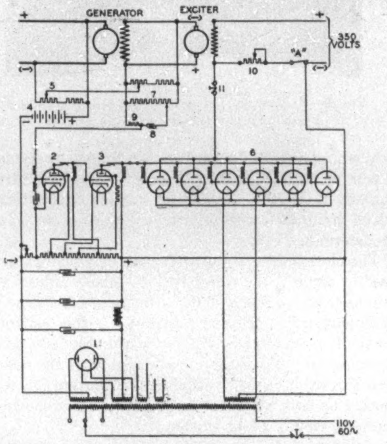

FIG. 5—SCHEMATIC DIAGRAM OF ELECTRONIC VOLTAGE REGULATOR

The regulator, when in operation, will tend to maintain this voltage difference constant at 1.7 volts. Any deviation in this voltage difference is amplified by tube 3 and the power tubes 6, so that a minute change in regulated voltage will cause a considerable change in the current in the exciter field winding which is connected in series with the power tubes across a 350-volt direct-current source. To prevent hunting resistor 9 is connected in series with condenser 8 across potentiometer 7 which is connected to the exciter armature terminals. When the exciter armature voltage is decreasing as a result of regulator action when load is disconnected from the generator, condenser 8 will discharge through resistor 9, and the voltage drop thus created will oppose the initial voltage change on the grid of tube 2 caused by the increase in regulated voltage; and therefore stabilize the regulator operation.

The sensitivity of the electronic regulator is ± 0.2-volt or better, and the regulator will bring the regulated voltage back to normal in from 2 to 5 cycles as indicated by the oscillogram in Fig. 6 if the exciter is omitted and the power tubes are connected directly in series with the generator field winding. During this test full load was connected to a 5-kw shunt wound generator. In Fig. 7 is shown an oscillogram of the same load conditions, with a ½-kw shunt wound exciter used to supply the excitation for the generator. The speed of response of the regulator is apparent from Fig. 6, which indicates that the regulator tends to correct for the variations in regulated voltage due to commutator ripples, which were rather pronounced on this particular generator. The action of the anti-hunting circuit is indicated in Fig. 7. It may be seen that due to the anti-hunting action the exciter field current starts to decrease before the regulated voltage has reached the normal value.

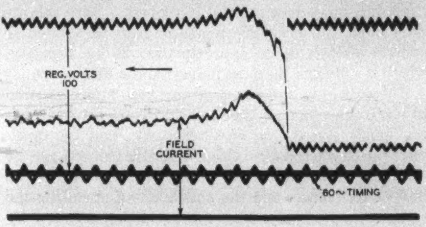

FIG. 6—RESPONSE OF ELECTRONIC VOLTAGE REGULATOR WITHOUT EXCITER

As shown in Fig. 5, the field rheostat for manual control 10 is connected so that when switch *A* is closed the field rheostat will be in parallel with the power tubes. In order to transfer from automatic to manual control, rheostat 10 is turned in and switch *A* is closed. The rheostat is then gradually turned out until the regulated voltage is 0.5-volt higher than normal, thus indicating that the current through the power tubes is zero. The field switch 11 may now be opened and manual control obtained by means of rheostat 10.

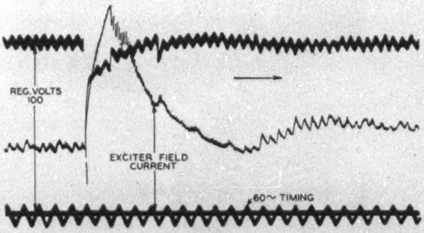

FIG. 7—RESPONSE OF ELECTRONIC VOLTAGE REGULATOR WITH EXCITER

The regulating range of the six RJ-563 tubes when new is 0.15 ampere to 1.2 amperes. At the end of the useful tube life the filament emission will, however, be slightly decreased, and for this reason the regulator is applied on the basis of a maximum current output of 0.9 ampere, thus giving a regulating range of 0.75 ampere. If the maximum exciter field current exceeds 0.9 ampere, switch *A* is not supplied, rheostat 10 is permanently connected in parallel with the RJ-563 tubes, and is designed to carry the no-load exciter field current minus the minimum tube current 0.15 ampere. With this arrangement the electronic regulator may be applied to control exciters up to approximately 20 kw capacity, which is sufficient for most industrial d-c generators.

The advantages of the electronic regulator compared to electro-mechanical type regulators are primarily, as previously stated, the high sensitivity and the quick response characteristic. Other desirable features are the simplicity of operation, the absence of maintenance, no radio interference, and the possibility of operating the equipment on board ship without being affected by rolling.

The electronic regulator has been successfully applied as a speed regulator for a single motor paper machine drive. In this case the motor was connected for armature control by means of a variable voltage generator, and the regulator was connected in the field circuit of the exciter which supplied excitation for the generator. A pilot generator geared to the motor served as the voltage indicator. In Fig. 8 is shown the electronic voltage regulator with covers removed. Fig. 9 shows the regulator mounted on a control board for a single motor drive having a 12 to 1 speed range.

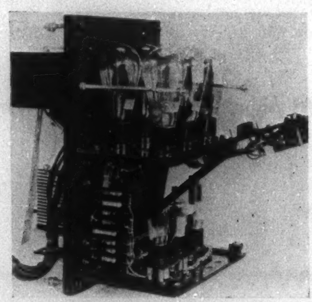

FIG. 8—ELECTRONIC VOLTAGE REGULATOR WITH COVERS REMOVED

## ELECTRONIC MOTOR STARTER

In applications where variable speed control of d-c motors over a wide speed range is needed, the conventional method of control is to supply a motor-generator set and to vary the generator voltage. An electronic motor starter shown in Fig. 10 which has recently been developed provides the means for adjustable speed control of d-c motors with an alternating current supply source. The electronic motor starter is equipped with phase shift controlled grid glow power tubes which are connected to supply armature voltage for the motor. A smooth armature voltage control during the entire range from zero to maximum is obtainable. The motor field is supplied with a constant d-c voltage by means of a pair of rectifier tubes. A desirable feature of this equipment is the automatic starting characteristic which limits the current during the starting period to a predetermined value.

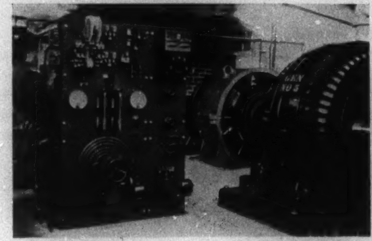

FIG. 9—ELECTRONIC SPEED REGULATOR INSTALLATION. SINGLE MOTOR PAPER MACHINE DRIVE

The electronic motor starter may be advantageously used in applications where frequent speed adjustments are made and where a smooth starting characteristic is of importance. A typical example is the control of manually operated coil winding machines where abrupt speed control may cause a wire break. At the present time this equipment is available for armature control of motors up to 5 hp, 230 volts. In Fig. 10 is shown an exploded view of a 3-hp starter.

## MISCELLANEOUS PHOTOELECTRIC CONTROL APPLICATIONS

The photoelectric cell with associated electronic equipment has long been extensively used for indicating and regulating purposes in various industrial processes, where the application of mechanical or electrical indicating devices would have been impractical. The use of photoelectric equipment for counting, sorting and inspection is thus rapidly increasing. Photoelectric equipment is often the only solution in counting applications where the objects to be counted cannot be arranged to operate mechanical counting devices due to the fragility of the material, due to the high temperature of the material, or due to the possibility of scratching a freshly painted surface. If the object to be counted is metallic, electrical circuits applying variations in capacity or inductance may be used; but in most cases it will be found that a photoelectric relay in connection with a light beam will give a more reliable indication.

If the object is fragile and non-metallic the application of photoelectric equipment is often the only solution for a successful installation. Photoelectric counting equipment is now being used commercially to count automobiles, sheets of paper, hot steel ingots, theatre patrons, incandescent lamp bases and a diversity of other objects.

Photoelectric equipment has been widely applied to initiate control operations where mechanical indicating means would not have been adequate. Photoelectric relays have thus been applied in paper mills as a paper break indicator, in steel mills to initiate shearing operations and to control soaking pit covers, and photoelectric equipment is extensively applied in elevator operation to prevent the closing of the elevator doors if a passenger is standing in the doorway. A manufacturer of window glass was confronted with the problem of indicating whether the glass sheet in leaving the oven had the correct width. Since the glass was plastic and red hot mechanical indicating means could not be used; photoelectric relays were installed and gave excellent service.

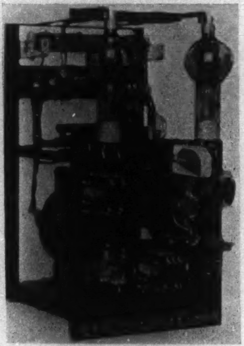

FIG. 10—3-HP ELECTRONIC MOTOR STARTER

Photoelectric lighting control relays are becoming popular as a means for controlling the illumination in offices and factory aisles, and experience with such applications indicates that frequently considerable savings in power consumption as well as increased production can be gained by the application of this device.

Photoelectric tubes in connection with amplifiers can be used to record small variations in light transmission through various substances. A commercial application of this is in the form of the photoelectric smoke indicator and recorder which may be applied to record the density of the smoke in the stack, and thus give an indication of the firing conditions. A similar application in a different field is the photoelectric indicator and regulator for concentration control. This equipment has been used to control the alkalinity of a copper solution in a copper refining process. Two photoelectric cells are connected in a wheatstone bridge circuit to control electronic amplifying equipment. The photocells are illuminated from the same light source. The light beam directed on one photocell is intercepted by a glass tube containing a sample solution having the desired alkalinity. The light beam illuminating the other photocell is intercepted by another glass tube through which flows the solution as used in the refining process. When the alkalinity changes, the color of the solution will change so that the balance of the wheatstone bridge is disturbed and through the amplifying system control relays are initiated which will change the speed of the lime feeding motor so that the alkalinity of the copper solution will be brought back within the proper limits. This scheme is described in more detail in a paper by J. V. Alfriend, Jr. (see page 512 of this issue).

The use of photoelectric equipment for sorting and inspection is increasing rapidly, and numerous applications in this field are working entirely satisfactory. The equipment may be arranged to initiate control relays which will remove from the production line an object which does not meet the specifications. For example, tin foil wrapped packages may be inspected by light reflection for proper labeling. If the paper label is in position the light will be reflected from the label and will be of low intensity, and the package will be carried forward on the conveyor. However, if the label is not placed properly, or is missing, the reflected light intensity is of high order and the control relays will be operated to divert the package.

In a similar manner inspection may be made for spots, holes or variations in color, although color inspection is a somewhat more difficult problem since the characteristic of the surface, whether flat or glossy, introduces complications.

The preceding paragraphs are not intended to cover the entire range of possibilities for profitable application of photoelectric equipment in the industrial field; but are merely intended to point out characteristic applications of light-sensitive equipment, in order to show its universal adaptability to almost any control problem which may be faced by industrial engineers.

---

## Discussion

**R. E. Hellmund:** Mr. Gulliksen's paper is new and additional evidence of the great versatility of electronic devices in industry. In fact it can truthfully be stated that aside from their many possible functions in the generation, control and conversion of electric power, these devices and their circuits can take the place of the more important human senses such as seeing, hearing and feeling; in the latter case they even excell the human being and equal, through capacity effects, the ability of the bat to feel the presence of objects without actually touching them. The other human senses, taste and smell, are usually of lesser importance in industry, but more recently the tasting of fruit by electrically metering and recording its acidity by the use of electronic devices and circuits appears to be practicable and I believe under certain conditions the detection of odors by these means has been considered a possibility. As far as industrial processes and operations are concerned, the electronic devices offer possibilities of indicating, metering, recording and in many cases regulating with a high degree of sensitivity and accuracy and if desirable at or from remote locations such values, quantities and properties as:

Dimensions
Weight
Volume
Numbers
Position
Liquid Level
Density
Pressure
Light
Color
Opaqueness
Transparency
Sound and Vibration
Speed
Acceleration
Strength of Material
Mechanical Stresses
Time and Frequency
Temperature

Furthermore such functions as adding, subtracting, subdividing, inspecting, noise analyzing, timing and many others can be carried out or governed by means of electronic devices and circuits.

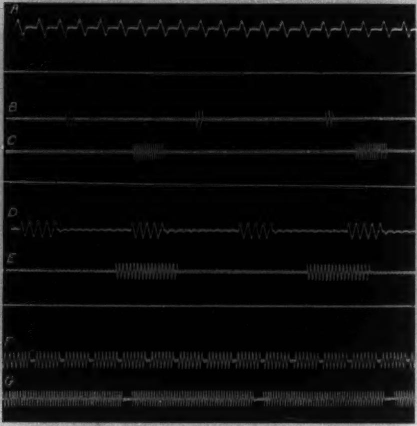

FIG. 1—OSCILLOGRAMS ILLUSTRATING RANGE OF CONTROL TO BE OBTAINED WITH GENERAL ELECTRIC CR7503-B2 THYRATRON-TUBE CONTROL FOR RESISTANCE WELDING MACHINES

*A*—1 cycle on, 1 cycle off
*B*—2 cycles on, 34 cycles off
*C*—15 cycles on, 95 cycles off
*D*—4 cycles on, 10 cycles off
*E*—17 cycles on, 36 cycles off
*F*—7 cycles on, 1 cycle off
*G*—47 cycles on, 4 cycles off

In view of the fact that many of these almost unlimited possibilities have been known for quite some time, the question is raised why the extent of the use of electronic devices in industry so far is, after all, very limited; to many this is most disappointing. Aside from the natural influence of the business depression and a certain reluctance to use new devices because of unfamiliarity with, and prejudice against them the answer to this question can be summed up in the one word "economics." Irksome as it may be to the enthusiast for the possibilities of these devices, economics will, in the best analysis, always be the governing factor. In the first place, while the electronic tube and its circuits are the parts making the particular device possible it must be appreciated that they are in many cases as far as the manufacturing and development cost is concerned, but a rather minor part of the entire device. The control of register in cutter applications described in Mr. Gulliksen's paper is a good example which shows the extensive and costly development required, in addition to the light sensitive tube proper, to accomplish the results. Naturally such expenses cannot be incurred unless they are economically justified by the particular application, either on account of extensive expected use and consequent quantity production or because of unusual benefits to the industry using the device. In many other applications the introduction of tubes has been retarded since the same result can under present conditions be accomplished by other means at a somewhat lower cost; an example of this kind is the motor control described in the paper. This condition is not necessarily inherent and permanent, but merely due to the fact that new tubes, now manufactured in small quantities have to compete with older highly developed and standardized devices. This condition can change only gradually as increased production brings about reduced costs which in turn will broaden the economic field of application and further reduce the costs.

These remarks, while explaining the present situation are by no means intended to dampen the enthusiasm about the possibilities of electronic devices in industry. Largely ignoring the present economics and gambling on the future, the designers have gone a long way in developing numerous applications at very considerable expense. It is now to be hoped that the users take an equally progressive attitude and at least partly discount slight economic handicaps as they appear at this time. Such an attitude can be well justified, because there are very frequently intangible advantages, which only become apparent after initial use. In this connection the early days of industrial electric heating may be recalled. The principal point then under discussion was the cost of electrical heat units as compared with fuel heat units and from this point of view the comparison did not look very favorable to electric heat. Since then so many advantages of electric heat such as automatic control, improved quality, reduced rejects, improved working conditions, possibilities of continuous flow production, etc., have become apparent that the heat economy has become of secondary importance in many cases. Quite similar conditions are already becoming apparent in many of the tube applications and industry as a whole is likely to benefit materially by an open minded progressive policy towards this new tool even in cases when the factors which

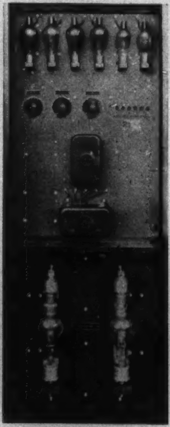

FIG. 2—THYRATRON CONTROL FOR RESISTANCE WELDING MACHINES WITH THYRATRON SYNCHRONOUS TIMER

are known and subject to figures at this time do not definitely show great economic advantages.

**W. R. King:** Concerning the description of the electronic time delay relay and particularly the statement referring to its use in connection with spot welding machines, I should like to point out that the successful welding of some materials depends upon the accurate timing of the application of power for periods as short as one or two cycles. This is particularly true in the case of many of the alloys being used at present. Mechanical interrupters and magnetic contactors are unsuited for this service, first, because of the inaccuracies inherent to such mechanical devices, and second, because they cannot readily be operated in synchronism with the system frequency. An electron tube system has been developed for the accurate control of resistance welding machines up to several hundred kilovolts. This system operates without mechanical contacts in the control circuit to control accurately the flow of current for periods as short as one cycle.

The system operates as follows:

The primary of a series transformer is connected in series with the primary of the welding transformer. Two power size thyratron tubes are connected to the secondary of the series transformer. When these two tubes are conducting, the series transformer secondary is effectively short-circuited and the primary impedance is reduced to a minimum, thus permitting practically full current to flow in the welding circuit. When the tubes are not conducting, the series transformer secondary is open-circuited and the primary impedance is high. In this condition the current is limited to the exciting current of the transformer, a value which, for purposes of welding, may be considered as practically zero. By proper control of the thyratron grids, these tubes may be made to conduct when desired.

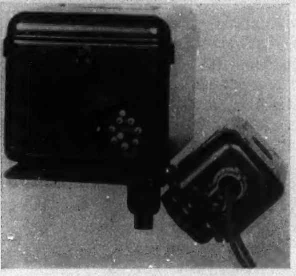

Fig. 3—Scanning Head for Photoelectric Paper Cutter Register Control

The grids of the power thyratron tubes are controlled by the thyratron synchronous timer, a system of smaller thyratron tubes. The thyratron synchronous timer consists of a timing circuit which, in the case of intermittent line welding machines, controls the time of the total welding cycle ("on" plus "off"), and a ratio-control circuit which controls the relation between the time "on" and time "off." The ratio-control circuit, the timing circuit, and the power control circuit all operate in synchronism with the system frequency and thus accurately maintain the time of the "on" period and the "off" period.

As the equivalent is used on spot welding machines, a small cam switch on the drive shaft controls the approximate starting time. The thryatron synchronous timer controls the actual starting time and also the length of the "on" period for the one spot weld.

The oscillogram in Fig. 1 show the accuracy and range of control. It will be noted that each "on" period corresponds exactly with each other "on" period for the same adjustment, even for "on" periods as short as one cycle.

A typical control panel is shown in Fig. 2. This particular panel may be used for either spot or line welding. The dials and switches for adjusting the timing are conveniently located on the front of the panel. The use of this equipment in connection with spot welding machines permits an accuracy hitherto unattainable. Used with intermittent line welding machines it permits, in addition to the accuracy of control, operation at speeds (*i. e.*, spots per minute) far in excess of those permissible with mechanical or magnetic circuit interrupting devices and of course the frequent replacing of contacts and mechanical parts is eliminated.

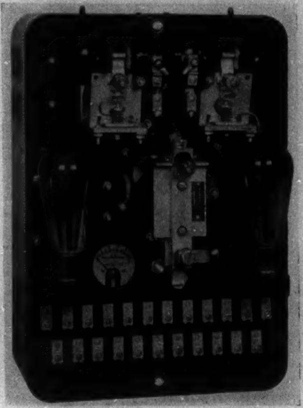

Fig. 4—Thyratron Panel for Photoelectric Paper Cutter Register Control

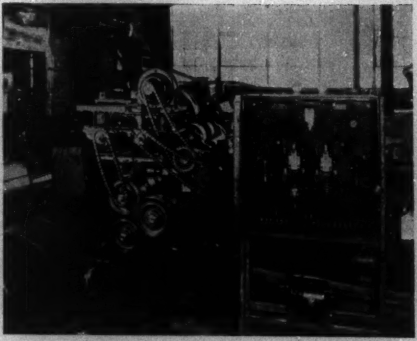

Fig. 5—Photoelectric Paper Register Control on Machine for Cutting Paper Bags

Mr. Gulliksen has presented a clear description of the operation of the photoelectric paper registry control system. We have found that in most applications, it is necessary to make a slight change of speed ratio between the cutter and draw rolls, as well as the position change. The speed ratio change is necessary to take care of the shrinkage and stretch of the paper and also because it is exceedingly difficult manually to adjust the speed ratio so that it is exactly correct. The position change brings the web back into registry and a relatively small speed ratio change tends to prevent it from getting out of register.

On those applications that require very high speed response, the time constant of the cable connecting the phototube to the amplifier becomes an important factor. When you consider that the time for response to a one-sixteenth inch spot traveling at 600 feet per minute is only about 1/2,000 second it is obvious that the interconductor capacitance of the phototube cable cannot be very much if the minute change in phototube current is to have any appreciable effect upon the grid voltage of the amplifier tube. To overcome this difficulty a "scanning head" has been developed, see Fig. 3. This is a small unit in which are mounted the phototube and its optical system, the amplifier tube, and the light source with its optical system. Thus the leads in the high impedance phototube-amplifier circuit are reduced to a few inches. This greatly reduces the time constant of the circuit and makes it possible to respond to impulses lasting only a few microseconds. The amplifier tube is connected to the thyratron panel by means of multiconductor cable. Since the amplifier anode circuit is of far less resistance than the grid circuit, interconductor capacitance in this cable has little effect upon the system. On the thyratron panel, illustrated in Fig. 4, are mounted the two thyratron tubes and the contactors which they control, and a time delay relay of the flux decay type.

The installation shown in Fig. 5 has been in service in the plant of the Jaite Paper Company, near Cleveland, since 1931. This is one of a number of installations on bag-making machines.

# The Use of Communication Facilities in Transmission Line Relaying

BY J. H. NEHER*

Associate, A.I.E.E.

***Synopsis.***—*This paper outlines the fundamentals of a method of obtaining overall protection of transmission lines by a comparison of the relative direction of fault current flow at the line ends by means of a communication system. The results obtained are equivalent to differential protection. The carrier-current pilot or d-c pilot wire schemes which have been introduced during the past few years are applications of this method.*

*The optional use of a communication system to link the trip circuits at the ends of a transmission line provided with any conventional form of relay protection is described. This insures the simultaneous tripping of both line ends for all fault positions.*

*The various types of communication systems adaptable for relay purposes are described and discussed in regard to coordination with the telephonic communication, telemetering or supervisory control systems employed as adjuncts of the power system.*

* * * * *

## INTRODUCTION

THE large size and complexity of the modern power system and the attendant problem of maintaining system stability at times of system faults have indicated the desirability and often the necessity of clearing faults on the major transmission lines of the system with the utmost rapidity. To meet this requirement high-speed circuit breakers and high-speed relays have been developed. The step-by-step distance relay has been evolved which permits the instantaneous clearing of faults over a greater portion of the line than was previously possible where balanced relays could not be used. The protection afforded by the selective timing relay schemes, however, even when reduced to a high-speed basis, falls short of the ideal in several important respects.

1. Faults at a line end, either in the case of a parallel line installation where balanced relays can be used, or in the case of a single-line installation where distance relays or the equivalent must be used, cannot produce instantaneous tripping at both line ends and sequential tripping at best must result at the station distant from the fault. In power systems comprising both steam and hydro generation, this necessary increase in the total clearing time may be sufficient to throw the hydro units out of step.
2. At the present state of the art, the distance relay is not entirely fool-proof when applied to protection against ground faults. Equivalent systems for determining distance on ground faults by measuring the residual current are not universally applicable.
3. In certain complicated systems it is difficult to make the step-by-step distance relays on one line section select with the relay equipment on adjacent sections without some sacrifices in the time of operation for faults in the section protected.

It is natural, therefore, that considerable interest should be shown in the development of systems of *overall protection* for transmission lines. This form of protection, which will trip both line ends instantaneously for all faults on the line, and which is non-operative for systems faults not on the line, and therefore inherently selective, represents very nearly the ideal relay system. Overall protection employing *differential* relays, *i.e., differential protection*, has been used to some extent for the protection of short transmission lines; but the cost and complication of providing a group of a-c secondary or *pilot* wires paralleling the transmission line with the attendant difficulties of maintaining these pilot wires, keeping them free from induced effects, and handling the high-current transformer burdens involved has prevented the widespread use of this method.

During the past few years overall protection has been successfully accomplished on a number of transmission lines throughout the country by the application of methods whereby the relative instantaneous directions of residual current, or the relative directions of fault current flow at each end of the line, are compared by a communication system which is arranged to trip both ends of the line when the relation obtained indicates that the line is faulted. These methods, while differing as to the details of the relay or the communication systems used may be given the title *directional comparison.* Overall protection by directional comparison using a communication system as the auxiliary link between the line terminals has advantages over differential protection because a reliable communication system can be provided more readily and at less expense than a-c pilot wires.

Communication facilities may also be employed as an adjunct to a selective timing relay system of any type to permit the simultaneous tripping of the breakers at both ends of the line upon the operation of the relay system at either end. This system, which may be termed *transferred tripping*, is useful in cases where selective timing relay systems may be employed to give instantaneous operation at one end of the line under all fault conditions; and where, due to stability considerations it is necessary to trip both line ends instantly without waiting for sequential or second zone operation at either end.

The communication facilities required for either of

*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

these protective schemes are those of a telegraph system. The medium employed may be the transmission line itself by means of carrier-current, or else telegraph or telephone circuits either owned by the power company or leased from a telephone company. The choice of the particular communication system to be used will depend upon a wide variety of local conditions and considerations. It is the purpose of this paper to discuss these various systems from the standpoint of their individual characteristics, and also to indicate the possibilities for the correlation of the relay communication system with the telephonic communication, telemetering, or supervisory control systems which may be simultaneously employed.

### PRINCIPLE OF OPERATION

*Overall Protection by Directional Comparison.* The underlying principle of operation of the *directional comparison* method of relay protection is based upon the fact that the presence or absence of a fault on a transmission line can be determined from a knowledge of the relative directions of power flow at each end of the line. As an example, consider the usual case of a transmission line running between two stations, each of which is connected to a generating source, and assume that this transmission line is provided at each end with a power directional relay arranged to close its contacts when power flows into the line at that end. With this arrangement it will be seen that under conditions of normal power transfer over the line in either direction, the contacts of the directional relay at the receiver end of the line will always be open. This same condition holds in the case of a through fault in either direction.

If a fault occurs on the line, however, the presence of generating capacity at both ends of the line will cause the flow of power at each end of the line to be towards the fault with the result that both directional relays will be closed. Conversely, it follows from what has been said that the simultaneous closure of both directional relays indicates that the line is at fault. If a system of communication is set up between the ends of the line whereby the fact that both directional relays are closed at the same time may be established and made known at each end of the line, we have the essential elements of a relay protective system which performs in exactly the same way as the conventional system of differential protection.

Of course this arrangement presupposes that the directional relay at each end of the line will always function as intended under every fault condition which may occur on the system regardless of the type or location of the fault. This requires that particular attention be paid to the design of the directional relay system used at each end of the line, but it is possible to design this equipment so that all conditions can be met, even when either end of the line protected may not always be connected to a generating source. In the case of tapped lines, it may be necessary to install a directional relay system at the end of the tap and to connect the communication system to this point as well.

It may be well to point out here that this relay system is not particularly well suited to the protection of a piece of equipment which may develop partial faults such as turn-to-turn faults in a generator, motor or transformer. It is desirable to clear such faults to prevent further damage to the equipment, and they can be cleared if the more sensitive types of differential protection are used. With the directional comparison system, it is impossible to do this because power flow would continue through the equipment and one of the directional relays would remain open.

A transmission line, on the other hand, cannot develop a fault between phase wires and continue to transfer power over the phase affected. While this may be possible in the case of a ground fault on a transmission line, this condition is cared for in the design of the directional relay system by the addition of a ground relay so that the system will function correctly on ground faults as well as phase faults.

The communication system, which is considered as including the mechanism whereby the relative indications of the two directional relays are compared and the tripping operations initiated as well as the actual medium of communication, may be considered as a telegraph system. In its simplest form it consists of a conventional d-c telegraph circuit between the ends of the transmission line in which the *keys* are actuated by the directional relays and the *sounders* are replaced by auxiliary relays arranged to trip the circuit breakers. This arrangement is shown in Fig. 1. This circuit automatically compares the relative directions of power flow at the ends of the line and initiates the tripping operations under proper conditions, since current can flow in the telegraph circuit and through the tripping relays only when both directional relays are closed at the same time.

In practise, the single directional relay shown is usually a directional relay system consisting of a group of relays designed to operate properly under all possible fault conditions. Furthermore, the system is so arranged that the *keys* are actuated only when there is a fault on the power system, so that under normal conditions the *keys* at both ends of the communication circuit are open irrespective of whether or not load is being carried over the line. Stated another way, the directional relay system is inherently a *fault detector* as well as a *directional detector*. This arrangement is necessary, as will be shown later, to secure the most reliable operation from the communication system.

There are several directional relay arrangements which are suitable for use with this protective scheme. In the case of protection against phase faults, a single directional relay of the polyphase type or else three single-phase units may be used. If the line is provided with directional phase or ground relays for back-up purposes in addition to the overall protection, the directional elements of these relays may be used to control the overall protection, provided the contacts of these directional elements are placed in the trip circuit of the relays as is often the case. When single-phase directional elements having true or approximate wattmeter characteristics are used, it is necessary to associate an instantaneous overcurrent relay installed in the same phase with each directional element. The contacts of the directional and overcurrent elements of each phase are connected in series and the three-phase groups connected in parallel. It is possible to have an unsymmetrical fault behind the group of directional elements of such a nature that one of the single-phase directional elements will reverse and close its contacts. The phase on which this can happen will be carrying a relatively small current, however, so that the introduction of the overcurrent element set at the proper value will prevent the group of directional elements from closing the control circuit of the protective scheme.

These overcurrent elements also prevent this control circuit from being closed at either end of the line due to the flow of load current, which is necessary for the proper operation of the scheme. When a polyphase directional relay is used, it must either be provided with voltage restraining coils which will hold the contacts open under load conditions or else be supplemented by a set of overcurrent elements to accomplish the same result.

Some single-phase directional elements are provided with voltage restraining coils so that their contacts are normally open under flow of load current and have operating characteristics such that the use of additional overcurrent elements are not necessary if they are used to control the protective scheme.

The directional elements of ground relays are normally open so that an overcurrent element is not strictly necessary, but the use of such an additional element may be considered desirable to reduce the sensitivity of the device.

It has been assumed so far that there is a source of fault current supply at each end of the line. The system can be made to function in case there is not a source of fault current supply at one end by replacing the directional relay at that end by an equivalent system such as an instantaneous overcurrent element and an instantaneous undervoltage element in each phase. The first element is circuit opening on overcurrent and the second element is circuit closing on undervoltage. The contacts of the two elements are connected in series. Normally the control circuit is open due to the presence of voltage on the transmission line, but if the phase under consideration is faulted the voltage will drop causing the voltage element contacts to close. If this condition is caused by a through fault, however, the current element contacts will open before the voltage element contacts can close so that the control circuit will not be closed. If the fault is on the line the current element contacts will not open, so that the control circuit will be closed as soon as the voltage element contacts have closed. A somewhat similar arrangement can be made to secure correct operation on ground faults.

Other possible arrangements suggest themselves. When there is sometimes but not always a source of fault current supply at either end of the line, it is necessary to use both a directional relay and the above combination of current and voltage elements or some equivalent arrangement.

Under certain conditions, the phase relay system may operate incorrectly at times of ground faults. When this can occur it is necessary to provide both a phase and a ground relay system and to interlock the two systems so as to render the phase relay system inoperative when there is flow of ground current.

*Transferred Tripping.* In this arrangement, the communication system is used as an adjunct to a standard relay protection scheme either of the balanced current or step-by-step distance type in order to insure instantaneous tripping of both ends of the line under all conditions of faults occurring on the line. It is assumed that the relay protective scheme is of such nature that instantaneous tripping may be secured at, at least one end of the line for any type or location of fault on the line. The communication system, arranged as shown in Fig. 2, merely serves to trip the other breaker as soon as either breaker trip coil is energized.

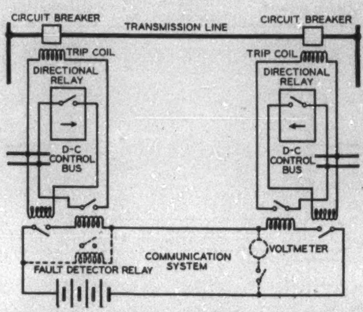

Fig. 1—Diagram Showing the Use of a Communication System to Obtain Overall Protection by Directional Comparison

While this method is similar to the directional comparison method in that instantaneous tripping for all fault positions on the line is obtained, its selectivity in the case of external faults depends upon the selectivity of the relay protection scheme at either line end. This relay protection scheme will be more complicated and costly than the directional relay system required by the directional comparison method. On the other hand, the line is completely protected, even if the communication system fails to operate. The directional comparison method will probably be the more desirable in the majority of cases, although transferred tripping may be useful in certain instances where selective timing relays are already installed or where there is an objection to the use of a communication system as a component part of the first line of defense. Either method requires a communication system of substantially the same form which must be as fast and as reliable in operation as possible.

## TYPES OF COMMUNICATION SYSTEMS

The types of communication systems which are adaptable to this service are the d-c telegraph, the low-frequency rectified a-c pulse telegraph, carrier-current, and the voice-frequency telegraph. These systems will be described as applied specifically to the directional comparison method only, but the modifications required to adapt them to transferred tripping are self-evident.

*D-C Telegraph.* The fundamental circuit of the d-c telegraph system has already been shown in Fig. 1. With this arrangement, however, it is evident that a short circuit on the telegraph line will cause the line to be tripped at the end at which the telegraph battery is located if the directional relay system at that end is closed, irrespective of the operation of the directional relay system at the other end. This would result in an incorrect operation in the case of a through fault on the power system. For this reason, it is necessary to provide the telegraph circuit with a monitoring system which will detect faults on this circuit and automatically render the relay system inoperative before a through fault is likely to occur. This can be done by normally energizing the telegraph circuit through the coil of a sensitive *fault detector* relay as shown in dotted lines in Fig. 1. This fault detector relay may be arranged to lock open the telegraph circuit and give an alarm.

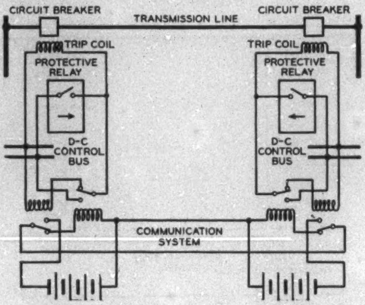

FIG. 2—DIAGRAM SHOWING THE USE OF A COMMUNICATION SYSTEM TO OBTAIN TRANSFERRED TRIPPING

Whenever a through fault occurs on the power system in such a position that the directional relay system at the end away from the battery will close, this will close the telegraph circuit through the fault detector relay. It is therefore necessary that the fault detector have sufficient resistance to keep the flow of current below the operating point of the tripping relay at the distant end; and since the fault detector relay will operate, it is necessary to introduce a time delay in the lockout feature so that such a system fault can be cleared before the telegraph circuit locks out.

The telegraph circuit can be checked for continuity at any time by introducing a high resistance voltmeter at the end away from the battery, as shown by the dotted lines in Fig. 1. It is possible to secure an automatic indication of continuity by substituting a sensitive undervoltage alarm relay for the voltmeter, but this relay must have a sensitivity greater than the fault detector relay and sufficient resistance to keep the normal flow of current below the operating point of the fault detector relay.

The conventional d-c telegraph circuit employs a single wire with ground return. While this arrangement is theoretically suitable for use in this connection provided the grounding points of the telegraph circuit are made at considerable distances from the power system grounds, it is not in general as safe or reliable for this particular service as the two-wire or metallic circuit grounded at only one point.

The details of equipment and circuit arrangement will vary to a great extent with local conditions. In general, it is desirable to incorporate as much of the equipment associated with the telegraph circuit as possible in a single case so that it may be treated as a unit similar to a power relay. Fig. 3 shows the relay assembly used by the Philadelphia Electric Company at the battery end of the circuit consisting of circuit closing, tripping, fault detector, lockout and oil dashpot relays, the latter being used to give a time delay to the lockout function. Fig. 4 shows the relay assembly used at the other end of the circuit comprising circuit closing and tripping relays, together with a voltmeter for checking the continuity of the circuit. This latter assembly was designed for a 10,000-volt insulation between the telegraph circuit and the station control circuits which is required for all telephone circuits entering the particular station in which this relay assembly is located.

At the present time, to the writer's knowledge, installations of over-all protection by directional comparison employing the d-c telegraph have been made by the Oklahoma Gas and Electric Company[1], the Duquesne Light Company, the Los Angeles Gas and Electric Corporation,[2] the Tennessee Electric Power Company, and the Philadelphia Electric Company. The last four of these companies employ a two-wire metallic circuit either owned by the power company or leased from the local telephone company for each transmission line protected. The Oklahoma installation employs a grounded telegraph circuit derived from a simplexed telephone circuit which is also used for telephone conversation between the stations at the line terminals.

*Low-Frequency Rectified A-C Pulse Telegraph.* In general, two d-c telegraph circuits would be required for the protection of two parallel transmission lines. Although various modifications employing polarized relays and additional batteries may be made which permit the use of a single telegraph circuit, these arrangements are complicated and will not operate if both transmission lines are simultaneously faulted. In order to overcome these difficulties the arrangement shown in Fig. 5 is suggested, employing an alternating electromotive force of low frequency and suitable rectifying units acting as valves to control the flow of current through the tripping relays. The telegraph equipment of the upper line is operated by the positive half cycles of the voltage furnished by the alternator, while the equipment of the lower line is controlled by the negative half cycles. The use of low frequency is desirable to minimize the line reactance. The tripping relays must be designed to hold in over the opposite half cycles during which they receive no current. A standard 20-cycle ringing machine, continuously driven by a d-c motor from the station control battery would serve as the alternator, and standard copper-oxide rectifying units are suitable for use as valves. A d-c monitoring system may be readily adapted to the circuit.

---

[1] For references see bibliography.

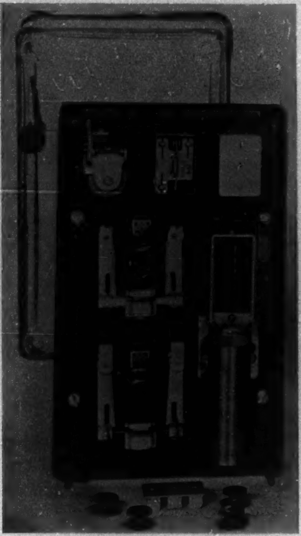

Fig. 3—D-C Telegraph Relay Assembly for Battery Station

This is a pulse system and must not be confused with an alternating current system. Care must be taken to prevent the current pulses from setting up counter electromotive forces in the circuit and for this reason transformers cannot be used as coupling or line insulating devices.

*Carrier-Current.* A carrier-current system of overall protection of transmission lines against ground faults has been in operation on the Southern California Edison System for several years.[3] In the manufacturer's original design of carrier-current protection, the relative instantaneous directions of the residual current at each end of the line were compared by means of the carrier-current equipment,[4] rather than the relative directions of residual current flow. This arrangement had several disadvantages, including the limitation that while protection could be secured against either phase faults, or ground faults, it could not be secured against both types of faults simultaneously with the same equipment. As a result the present form of this equipment offered by the manufacturer is based upon directional comparison of fault current flow and is therefore applicable to protection against all types of faults.[5,6]

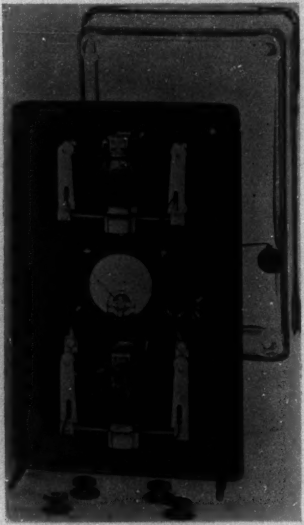

Fig. 4—D-C Telegraph Relay Assembly for Distant Station

The general arrangement of this equipment is indicated in Fig. 6. The line is equipped at each end with a carrier-current transmitter consisting of a vacuum tube master oscillator and power amplifier and a simple single tube receiver suitably coupled to two conductors of the transmission line. Since the transmission line is used as the communication channel, a short circuit between the conductors forming this channel would render the communication system inoperative. It is therefore necessary to arrange the equipment so that the signals transmitted are used to prevent, rather than to initiate, the tripping operations. This in turn requires the installation of traps in the transmission line to prevent external faults from interfering with the communication. The signal transmission at each end of the line is initiated by an instantaneous directional relay (transmitter starting relay) which is directional towards the bus. The back contacts of this relay on opening put the master oscillator of the transmitter into operation. A second directional relay (tripping relay) which has a slight time delay and is made directional towards the line initiates the tripping operation unless a signal is received before its contacts have closed. If there is a fault on the line, therefore, no signals will be transmitted or received and the tripping operations are allowed to take place. In the case of a through fault, the tripping directional relay starts to operate at the end where power is flowing into the line, but a signal is instantly transmitted from the other end, and is received in time to open the trip circuit before the contacts of the tripping directional relay have closed.

Fig. 5—Low Frequency Rectified A-C Pulse Communication System for the Protection of Two Transmission Lines

A single frequency (100,000 cycles) is used for transmission in both directions and the transmitters and receivers are tuned to this frequency. The filaments of the vacuum tubes are kept energized continuously, and the slight time delay required in initiating the tripping operation can be made as low as 3½ cycles with assurances of getting positive lockout on through faults.

Since the failure of either a transmitter or receiver equipment can produce tripping in the case of a through fault, some means of automatic supervision is necessary. This takes the form of a periodic timing device at each line end that momentarily energizes the transmitter. The associated receiver, being tuned to the same frequency, should respond and operate the receiver relay. The device is so arranged that an alarm is given in case the receiver fails to operate. By proper synchronization and arrangement of the supervising devices at the line ends, it is possible to check the overall transmission between stations and automatically to lock open the trip circuit at either end in case a signal is not received from the other end at the appointed time.

*Voice-Frequency Telegraph.* A system of voice-frequency telegraphic communication suitable for the transmission of twelve messages simultaneously over a telephone circuit is in use by the American Telephone and Telegraph Company.[7] This system operates on the principle that a different frequency is used for each telegraph channel. The twelve frequencies are superimposed on the telephone circuit and separated at the receiving end by band pass filters after which each frequency is rectified and permitted to operate a receiving telegraph relay.

This system may be readily adapted for relay communication as shown in Fig. 7. When the directional relay at either end of the transmission line closes, it permits the voice-frequency transmitter associated with it to transmit a signal of a definite frequency over the telephone line. The receiver system at the other end of the transmission line is tuned to respond to this frequency and to this frequency only. The system is arranged to trip the line when a signal is received at either end at the same time that the directional relay at that end is closed. The transmitter at one end of the line must be prevented from operating the receiver at the same end; this may be done by using two frequencies for each transmission line or else by substituting a *bridge transformer* for the repeating coil shown on the diagram. Such arrangements will keep the transmitted

frequency out of the receiver, so that both transmitters associated with one transmission line can operate at the same frequency thus permitting the protection of twelve transmission lines with a single telephone circuit.

A suggested design of the voice-frequency telegraph equipment incorporating the transmitter and receiver in a single unit operative from a 250-volt power station control battery is shown in Fig. 8. The filaments of the vacuum tubes are continuously energized and the equipment is put into operation by the directional relay which applies plate potential to the tubes.

## SELECTION AND COORDINATION OF COMMUNICATION SYSTEMS

The selection of the type of communication system best suited for the protection of a given transmission line involves a great number of considerations, many of which are beyond the scope of this paper. In general the type of relay communication employed should be closely coordinated with the type of telephonic communication used between the power stations involved. For instance, if the transmission line is equipped with a carrier-current telephone, the natural choice of relay communication would be the carrier-current type utilizing the existing coupling devices which represent a major part of the cost of this system. And where telephone circuits, whether leased or privately owned, are the most economical means of telephonic communication, the relay communication should utilize, if possible, the same or similar circuits.

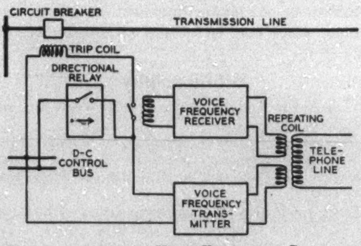

FIG. 7—ARRANGEMENT OF VOICE-FREQUENCY COMMUNICATION SYSTEM

In comparing the carrier-current system with the systems employing telegraph or telephone circuits, an important difference should be noted which arises from the use of the transmitted signal to prevent rather than to initiate tripping. In the case of the carrier-current system, failure of the communication equipment will not interfere with the tripping of either end of the line for faults on the line, but may result in the tripping of a line end on through faults in one direction, depending upon what part of the communication equipment fails. Substantially the reverse is true with the other systems, since the failure of the communicative equipment renders the protective system inoperative. Where suitable backup protection can be provided, it is generally more desirable to have equipment failure render the primary protection inoperative than to have it make the system susceptable to inselective operation. However, many exceptions to this principle will be found. With proper supervision of the equipment, the probability of experiencing serious system trouble as the result of the failure of either system is extremely small.

There is little choice between systems in respect to their speed of operation. The operating time of the carrier-current system has been given as 3½ cycles, but this time can probably be reduced slightly where it is necessary. Contrasted with this, we have the sum of the operating times of a directional relay and a tripping relay which determines the operating time of the other systems. This time cannot be made materially less than 1½ cycles. With the high-speed breakers available at present having operating times in the order of 8 cycles, the difference in operating times of the communication systems is negligible.

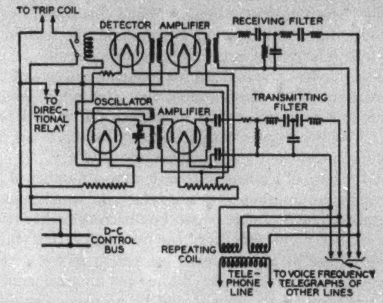

FIG. 8—DETAILS OF VOICE-FREQUENCY TELEGRAPH COMMUNICATION EQUIPMENT

The carrier-current system is not adaptable to the protection of cable lines due to the fact that the cable capacity furnishes an effective short circuit across the line and thus prevents the passage of the signals.

Where telegraph or telephone circuits are used, these circuits will, in the majority of cases, be leased from the local telephone company. In this event, certain restrictions are placed on the circuits as to the magnitude of the voltage applied and current circulated; and also, in certain cases, a high degree of insulation strength will be required between the communication circuit and the power station ground or control circuits.[8] These conditions may be complied with by the suitable design of the communication equipment in the power stations.

In order to prevent interference with these circuits in the telephone exchanges through which they pass, special tagging may be employed, such as has become the custom with radio broadcasting circuits. The use of monitoring devices will indicate at once the occurrence of trouble on the circuit and the modern telephone plant is so equipped that most trouble can be rectified in a very short time after it has been brought to the attention of the telephone company.

The d-c telegraph is the simplest and probably the most reliable form of relay communication, but as it requires a separate circuit for each transmission line protected, the cost of leasing these circuits may become an insurmountable item. The low-frequency rectified a-c pulse telegraph permits the protection of two transmission lines between the same power stations with a single communication circuit. While this system is in the experimental stage and will probably be limited to use with relatively short communication circuits, nevertheless it offers possibilities for reducing the cost of the protection. The disadvantage that the failure of the communication circuit will invalidate the overall protection of two lines is not particularly serious if the circuit has a sufficiently high degree of reliability.

In the case of a power system having a number of interconnected stations within a relatively small area, a single telephone circuit might be run from each station to a central point, and all of the interconnecting transmission lines be given overall protection by use of the voice-frequency telegraph. While such an arrangement has not been tried, there should be no particular difficulty in constructing voice-frequency telegraph units along the general lines indicated in Fig. 8, which would be comparable in cost and reliability to the higher frequency units utilized with the carrier-current system. Under such conditions, the cost of carrying the few telephone circuits required might be considerably less than the investment in transmission line coupling devices and traps required by a complete carrier-current installation.

When the power stations terminating the transmission line are directly connected by one or more telephone circuits, it is often possible to superpose either the d-c or low-frequency rectified a-c pulse telegraph on such telephone circuits. Such superposition is accomplished by simplexing or compositing.[8] With respect to circuit facilities leased from telephone companies, it is the practise of certain of these companies to charge for their facilities on a channel basis. Where a talking channel and a superposed telegraph channel are both provided, the charge for each channel would be applied.

When telemetering or supervisory control is used between the power stations it may be possible to use the same circuits for relay communication as well, providing the two systems can be properly coordinated.

Undoubtedly, there are other communication systems or arrangements suitable for relay purposes which have not been mentioned, but the systems which have been discussed appear to be the most readily adaptable. In the final analysis the communication system is the heart of the protective schemes described. Communication is an art somewhat apart from relay engineering, and it is hoped that the few principles contained in this paper may be of some interest to those more familiar with this art in providing facilities suitable for relay purposes.

## CONCLUSIONS

The following conclusions may be drawn from the foregoing discussion:

1. Overall protection of transmission lines may be accomplished by comparing the relative directions of fault current flow at the terminals of the line. This arrangement resolves into a directional relay system at each end of the line interconnected by a communication system.
2. Directional comparison secures all the advantages of differential protection; and by substituting a communication system for a-c pilot wires, results in a simpler, more reliable and less costly installation.
3. The directional relay system required utilizes standard relays which in certain cases may be component parts of the normal or backup protection of the line.
4. A communication system can also be used to link the trip circuits at the ends of a transmission line provided with any conventional protection, thus insuring the simultaneous tripping of both line ends for all fault positions.
5. Several types of communication systems are readily adaptable for relay purposes. The choice of the particular system to be used is governed by local considerations, particularly in regard to possible coordination with other telephonic, telemetering, or supervisory control circuits employed as adjuncts of the power system.
6. The relay communication system is the heart of the protective scheme. The widespread use of transmission line protection by the methods outlined lies in the availability of communication facilities which are reliable and which may be secured without undue cost.

## Discussion

**E. E. George and W. R. Brownlee:** Mr. Neher's paper has brought out a number of significant facts regarding pilot wire relaying and it should also arouse a great deal of renewed interest in system protection by this method. In the light of our limited experience and study we are in accord with practically all of his conclusions.

The Tennessee Electric Power Company has in operation a 14-mile 110-kv overhead transmission tie line protected by a 7-mile loop of metallic telephone circuit. Full back-up protection has been provided. This pilot wire installation was completed on November 20, 1932, at which time a series of short-circuit tests involving arcs both phase-to-phase and phase-to-ground was made. The results of these tests showed that very rapid and accurate protection was secured by means of pilot wire protection. None of the difficulties which were formerly experienced in connection with induced currents or voltages was encountered. However, it was found that the pilot wire itself would draw enough charging current when the contacts at one end only were closed to cause the tripping relays to operate occasionally. This was corrected by means of connecting a 2-$\mu$f condenser across the coil of each tripping relay. The few system operations since this time have been correct in that the pilot wire protection has cleared all faults within this section very rapidly and has not operated in cases of through trouble. The d-c telegraph system was preferred on account of its simplicity and reliability particularly since we much prefer that a relay equipment failure should result in a circuit failing to trip when desired instead of causing various circuits to open incorrectly. The metallic telephone circuit is leased from the Southern Bell Telephone and Telegraph Company.

*Insulation.* For the auxiliary circuit closing relays and tripping relays this company uses a small relay provided with a vacuum contact in order to secure the required insulation between the telegraph circuit and the station circuits. Also the operating battery is leased from the American Telephone and Telegraph Company and is located at its exchange since it was necessary that both ends of the circuit should have high insulation. Even in cases where high insulation is not required at both ends it is desirable to compare the cost of dry batteries with the rental charge of a storage battery at the exchange. The relative economy may depend on the load taken from the battery for supervisory purposes.

*Direction.* It has been found very advantageous to use 3 single-phase directional units with voltage restraint and with torque depending on phase angle for phase protection. This avoids the complication of additional overcurrent relays and the necessity of locking out the phase relays on the occurrence of ground faults. Potential amplification permits high speed at low voltages. In order to obtain the desired speed and sensitivity in case of single-phase faults to ground we prefer to add a high speed directional ground relay with its contacts in parallel with the phase relays.

*Line Tests.* When an overhead line has been cleared at both ends by relay protection it is customary to make a test on this line at full voltage from one end or the other. The usual scheme of pilot wire protection would be out of service for such a condition. Even if a combination of under voltage and current relays as described for use at stations where there is no power supply were added to each end of the line, correct operation could not be secured unless the potential transformers were on the line side of the oil circuit breaker.

We are considering the use of an auxiliary finger on the oil circuit breaker which is closed when the oil circuit breaker is open to be connected in parallel with the directional contacts at each station. Of course an insulating relay must be interposed if high insulation is required. If it is found impractical to coordinate the auxiliary fingers on the oil circuit breaker so that the *b* finger opens sufficiently ahead of the closing of the *a* finger (in series with trip coil) when the breaker is closed, the circuit of the *b* finger may be placed in series with a contact on the control switch which is open only during the time the control switch is being operated.

*Supervision.* An open circuit in the pilot wire or a battery failure can be detected readily with volt meters or possibly alarm relays whether the battery is located at one end or at the center of the loop. This company is experimenting with the use of neon lamps for this purpose on account of the fact that they can be noticed much more readily than volt meters. With good supervision it is likely that a short circuit on the pilot wire circuit would be detected and the pilot wire equipment removed from service before a short circuit would occur on the high tension system.

**G. B. Dodds:** It may be of interest to state that the use of communication facilities for transmission line relaying has not been confined to this country, but has also been used in both England and Australia. In the December 1932 issue of an English publication, the *Metropolitan-Vickers Gazette*, is an article on "D-C Pilot Wire System of Relay Protection" by C. M. Longfield and A. D. Stevenson. In this article reference is made to an installation made in Sidney, Australia, in 1929, which has been in successful operation since that time. Additional reference also is made to this type of protection in the *Bulletin of Institution of Engineers*, Australia, Volume 5, No. 20, October 1928; and also in a paper on "Recent Developments in the Protection of Three-Phase Transmission Lines and Feeders" by Messrs. Ross and Bell, *Journal of the I.E.E.*, July 1930.

It is significant that in England, where various forms of a-c pilot wire protection have been used extensively and considered to give the most reliable and satisfactory protection (where its cost was not prohibitive), they are considering the use of this new principle of protection.

It is also of interest to note that in the systems described in English literature, a majority of them operate on what is termed the "lock-in" principle, that is, considering a ring feed, in which a number of automatic breakers are in series, only the breaker closest to the fault would be permitted to trip, while the other breakers were locked-in by having their trip circuits opened by the initiation of the relay closest to the fault. This is similar in principle to the operation of the carrier-current protection referred to in Mr. Neher's paper.

This new type of protection will serve as a valuable adjunct to the protection methods now in use. It will permit the solution of many difficult protection problems which otherwise could not be solved except by a more expensive means. However, it will not supplant the many established forms of protection now in use, but will rather supplement them as an accessory tool. It is not believed that the older forms of a-c pilot wire will be altogether superseded as it is still felt that, particularly on short transmission loops, the old type of pilot wire protection will cost no more and will have some advantages—one of which is that no potential transformers are necessary.

**A. F. Rose:** In dealing with the selection of communication systems the author mentions that an important distinction between power line carrier channels and other types of circuits which do not depend on power line continuity, is the use of the transmitted signal in the first case to *prevent* breaker tripping, whereas with the isolated communication channel the signals are used to *initiate* tripping. Where a power line carrier system is used, there are obvious reasons favoring the use of the former type of tripping control whereas with an isolated communication channel which is dependable, the choice between the two types of tripping control need not be biased by the communication channel limitations. Also, the isolated communication channel permits changing from one type of tripping to the other in the event changes in the power network make this desirable in addition to permitting the initiative method which the author generally prefers. The use of isolated communication channels, therefore, seems generally most desirable.

The author also mentions the restrictions on voltage and current which are involved in cases where the circuits are leased from the Telephone Company and that these requirements do not ordinarily limit the practical operation of the overall protection system. In some cases, however, the types of terminal apparatus may cause sufficient wave form distortion of the voltage or current in the leased circuit to react unfavorably on other nearby communication circuits. As pointed out in the report of the Subcommittee on Telemetering, Supervisory Control, and Associated Communication Circuits presented at the Cleveland meeting last year, most of the manufacturers plan their equipment so as to avoid this reaction. In cases where this has not been done by the manufacturer the extent of the reaction can be easily determined by test and, where necessary, corrective devices readily applied.

**E. H. Bancker:** Mr. Neher's paper is very opportune because it is becoming more and more apparent that it is difficult if not impossible for relays using factors available at one point of a system to provide the speed and selectivity desired and also to distinguish between fault and subsequent oscillation conditions.

The three electrical dimensions of an alternating-current system are voltage, current, and the angle between them. These three and time, are the only quantities available at any point whereby relays situated there may attempt to determine that there is a fault and ascertain its whereabouts. Almost every conceivable combination and permutation of these quantities, products, differences, and quotients, has been employed singly and in groups, and the result is an ever rising standard of performance that, as pointed out by Mr. Neher, is still somewhat removed from the ideal.

In view of the many ingenious ways in which current, voltage, angle, and time have been combined there would seem to be rather faint hope that any further combinations will greatly improve the performance of relays dependent upon them. The solution appears to be to go elsewhere on the system for further analytical data and to what more obvious place than the other end of the circuit in question? The familiar differential and pilot methods of protection used this principle by bringing together for comparison the magnitude and/or phase angle of the terminal currents.

There are both technical and economic limits to the distance over which such information may be transmitted but if some form of comparison, such as power direction, can be made locally and the result translated into contact position, any reliable telegraph channel is suitable for conveying information from one end of a circuit to the other. This is the important thing to be borne in mind because, although communication and protective relay arts have scarcely impinged on each other heretofore, both are highly developed and the protection engineer should not feel that he is venturing on untrodden paths in considering the use of a simple communication system to augment an almost standard group of relays.

The principles employed are so fundamentally sound and simple and the necessary devices of so nearly standard construction that the next few years should witness widespread acceptance of the idea of bringing communication facilities into protective practise. If this prophecy is fulfilled there will result not only faster clearing of faults but also a new freedom for the system designer and operator. The restriction to parallel operation of lines imposed by balanced relays will no longer apply if there are any reasons for doing otherwise. For example pairs of lines which are now tapped to serve some intermediate load areas may be rearranged as a series of loops. Faults will be cleared more rapidly and each station will have a feed from both directions with no increase in the number of breakers. Thus in the event of double-circuit faults, service still will be maintained. Lines of more than two ends are as easily protected as simple lines if the communication channel is available. Ground faults receive as good protection as those involving two or more wires, a feature that may not be required from stability considerations but one which is highly desirable nevertheless. Twin-circuit faults of any nature should clear as rapidly as single-circuit faults. This may become of increasing importance, because as efforts are made to render circuits immune to lightning, many single-circuit outages will be avoided but the remaining disturbances probably will increase the percentage (not number) of double-circuit faults.

Although much more could be said the foregoing is sufficient to indicate that there are many benefits to be derived from changes in relay practise, such as are outlined in Mr. Neher's paper. Believing this to be the case the General Electric Company has been active in the development of a carrier pilot protective system in which the carrier current equipment is assigned the simple task of indicating at one or more stations the position of power directional relay contacts at some other station. The articles mentioned in Mr. Neher's bibliography describe the system and tests made upon it.

Carrier has been selected as the most desirable medium of communication because as used, the channel must be reliable when it is wanted which is during external faults. If the line itself is not capable of serving as a communication channel, it is either because it is faulted or open-circuited. In the former case it is not needed as a communication link because the carrier is not sent out during internal faults. In the latter case there is no current to operate the tripping relays, so it is immaterial whether the channel is intact or not. It is recognized that although other communication facilities might serve to convey the required impulse, a transmission line carrying current to a fault elsewhere provides a self-checking channel of the greatest reliability. Therefore, unless alternative means effect a considerable saving, or there are technical obstacles to its use, it is believed that carrier is the most satisfactory of the communication channels avilable for pilot relaying.

**H. P. Sleeper:** Mr. Neher has made a very important point that attention should be given to the matter of the overall protection of transmission lines. Many of the ordinary relay systems in use today will disconnect one end of a transmission line rapidly but require a considerable time delay to effect the disconnection at the other end. Hence the simultaneous operation of the relays may be considered just as important as the factor of instantaneous disconnection.

Reviewing existing schemes of relaying, and interpreting this restriction literally, this narrows down our field to some type of differential protection. Of these pilot wire protection is the simplest. Formerly such protection made use solely of the a-c circuits and resulted in engineering problems of considerable magnitude.

Mr. Neher's paper describes a very ingenious method of overcoming such difficulties by effecting the differential action with the d-c control circuits only. This unquestionably is a distinct step forward in the art of differential protection. It has, however, the economic disadvantage of high cost, which is common to all schemes which use pilot wires of any type. This factor must be given serious consideration and may be prohibitive unless the engineering features of the scheme can be very highly capitalized.

There are substitutes for pilot wire protection, or overall differential protection to use a general term, in the nature of balanced protection between pairs of lines if available, and the use of schemes of current measurement, which, particularly in the case of ground protection, may be found to give instantaneous, simultaneous, or sequential operation of the relays on the ends of the lines. These schemes frequently offer an economic substitute for the more expensive pilot wire protection and offer only slight engineering disadvantages in comparison.

It is important to note, however, that none of these schemes offers a universal solution which can generally be applied to the protection of transmission lines in a complicated network. The scheme is yet to be developed which can be applied in all locations, which preferably cover both phase and ground protection of such lines, and which will economically meet all the requirements of ideal relaying. While all schemes of pilot wire relaying may fulfill the engineering specifications, the cost would rule out their common application. It is therefore important to note that while such schemes have been improved and simplified, as described in Mr. Neher's paper, they must continue to remain limited in their volume of applications for the reasons noted above. The panacea for the bulk of the relay engineer's problems is still undiscovered.

However the ills of time element relaying have been cured mostly by the use of relays of the distance type, as far as short-circuit protection is concerned. Ground distance relays are still unsatisfactory but progress is being made. It therefore seems quite possible that the ideal protective system which will operate on all ends instantaneously and simultaneously, for all types of faults, may be soon made available by combining relays of the distance type with some of the schemes described in Mr. Neher's paper, probably making use of the carrier current feature to avoid the disadvantage of pilot wires.

**C. A. Muller:** On modern power transmission systems the fast clearing of line faults is necessary so as not to upset the stability of the systems and further, to prevent prolonged voltage surges which cause customers' motors to drop off the line. The present schemes of high speed relaying, such as instantaneous overcurrent relays, definitely set to clear faults within a predetermined distance from the outgoing bus, balanced line relays, and distance relays of both the reactance and impedance types are each more or less limited in obtaining fast relaying under all conditions. It has been our experience that probably the most serious disadvantage of any of the above schemes is that they do not permit fast relaying when simultaneous trouble occurs on both circuits of a double-circuit line.

It has been apparent for a long time that the only method for accomplishing high speed clearing of faults 100 per cent of the times would be a relay scheme which would be equivalent to differential protection of the line section. During 1927-1928 we made a great number of field tests on a carrier current pilot system of relay protection to determine if the scheme was foolproof. Our experience with carrier current was such that we were satisfied that if the scheme could be made to operate satisfactorily it would give ideal protection. Although this original installation proved on field tests to have some serious defects, the results of these tests convinced us that the principle of employing carrier current in place of pilot wires was sound. After further study of this scheme of protection we became convinced that the only method to make it operate successfully was to employ carrier current solely for transmitting a signal from one station to the other station and to employ power directional relays at each station to determine whether the fault was internal or external to the section. Then, depending on whether the fault was external or internal, the directional relays would cause carrier current to be transmitted so as to block or not block the tripping relays as the case might be.

The outgrowth of this was the development of a very much simplified form of carrier current pilot system utilizing directional relays for actuation of carrier current and causing locking out of the tripping relays on through faults. An experimental installation of this type was made in Ohio on the Newark-Crooksville 66-kv line and field tests were made on it. The results of these tests[1] prove that this form of protection is reliable and can be depended upon to give satisfactory operation in a maximum time of four cycles.

Mr. Neher's paper presents very clearly the various other means in addition to carrier current that could be employed in place of pilot wires to obtain inherently 100 per cent protection of a line section with high speed relaying. In all of these schemes it is to be noted that power directional relays are employed at both stations to determine whether the fault is internal or external to the section and that the directional relays cause a signal to be transmitted from one station to the other station either to block or not block the tripping relays, depending on whether the fault is internal or external to the line section.

In regard to the employment of telephone circuits either leased or privately owned for pilot wires, it has been the experience on our system that the carrier current equipment is far more reliable than either leased or privately owned telephone circuits have been and that carrier current on a well-built transmission line could be depended upon to transmit a signal where all other means of transmission had failed.

**R. J. Wensley:** The application of protective relay systems should be studied rather carefully to ensure the selection of that system which will give the needed protection for the least cost. Due regard must be had for the importance of the service and the amount which can be spent for insurance of that service. Increased total loading limits due to improved stability is to be considered on the credit side of the evaluation when such increase in capacity is made possible by the increase in speed and certainty of selection of the relay system being considered.

The simplicity and high degree of reliability to be obtained by the use of leased pilot wires makes this form of high speed protection very desirable. The communication companies have made great strides in the perfection of their circuits, and a very high order of continuity is now available in the more thickly populated portions of the country. For short lines where leased pilot wires through "all cable" routes are available, it would seem probable that no other form of high speed protection would be as simple and as low in overall cost. As the lines increase in length, the annual rental cost rises in proportion and becomes uneconomical. Although conditions and cost vary with locality, voltage of line and other variables, it is probable that the limit of economical use of pilot wires will lie between 50 and 75 miles.

As a substitute for the leased pilot wires, there are three optional systems:

1. Specially built pilot wires.
2. Distance relays.
3. Carrier pilot system.

The first of these is almost obviously limited to cable systems within very short distances, usually inside the limits of a large city.

The second option has received much attention in recent years and much development work has been done to improve the speed and selectivity of such systems. It is possible to secure practically 100 per cent high speed protection for about 80 per cent of the transmission line and slightly delayed but fully selective protection over the remaining 20 per cent of the line. If the line is important and is loaded to such an extent as to approach instability, this 20 per cent portion cannot be tolerated.

The third option, carrier pilot systems, offers the only method by which long, important sections of line can be given fully selective, high speed relaying at a reasonable expense. There are many disadvantages which must be considered when carrier applications are discussed. None of these should be considered as bars to the use of carrier where such use is economically justified. But those making carrier applications should understand the limitations and the uncertainties of carrier operation.

Carrier systems require some form of coupling to the line. This grows increasingly expensive as the voltage of the line increases. Space must be provided in the substation structure for the coupling equipment. Series tuned chokes must be installed in the high tension lines to limit the carrier to a given section. Radio tubes of considerable capacity must be maintained in an energized condition at all times to be ready for instant service when needed. The resonant circuits of the receiver are liable to shock excitation which may be furnished by arcing grounds.

---

[1] "Carrier Current Relaying Proves Its Effectiveness," P. Sporn and C. A. Muller, *Electrical World*, September 10, 1932.

In spite of all these disadvantages, there is a definite place for carrier pilot systems and the above cautions are intended only as a warning to prospective users of carrier that there are many difficulties to be surmounted, and that the equipment should be applied with its limitations fully understood.

In any event, the transmission line should be fully protected by an adequate system of relays to obtain the best possible selectivity, should the carrier fail to perform. Should the application be properly made, the carrier will serve as an added feature to ensure high speed but which will not paralyze the system should it fail. There are many transmission links where the service is of such prime importance that the added cost of the carrier pilot is well justified. A few cycles may often be the margin between no interruption to service and a very messy interruption with plants out of synchronism and much service impaired.

**J. H. Neher:** The use of a battery located at approximately the middle of the direct current telegraph circuit, as mentioned by Messrs. George and Brownlee, is ideal in many respects, and permits automatic fault detection and lockout at the power stations if the minimum operating current of the tripping relays can be made sufficiently above the operating current of the fault detector relays, which would be arranged to close their contacts when the normal current through the loop departed in either direction from the prescribed limits. In order to make the direct current telegraph as insensitive as possible to surges, stray currents, etc., it is desirable to make the tripping current as high as is permissible, and to use enough battery voltage (within the permissible limits) to drive this current through the loop. In certain cases it may not be possible to obtain the requisite battery facilities in the telephone plant to work the tripping current up to its permissible limit.

With regard to methods for making the protective scheme operative in case one end of a faulted line is closed back on the bus, the simplest arrangement consists of an additional connection between the contacts of the directional relay and the trip circuit through a set of contacts on the breaker closing control button. As long as this button is held in the closing position, the line is automatically given instantaneous relay protection.

In connection with the use of direct current pilot wires in England, protection by this means was suggested to the British Institute as early as 1908. The method was similar to the direct-current pilot wire loop which has been described; although British development seems to have been along the lines of the "lock-in" or "interlock" systems, using the transmitted signal to prevent the tripping operations, as Mr. Dodds points out. A recent development termed "duplex" trips either end upon the simultaneous closure of the directional relay at that end, and the receipt of a signal from the opposite end, a duplex telegraph circuit being employed to permit the simultaneous transmission of two signals in opposite directions. It is not apparent that this arrangement has any advantage over the direct-current pilot wire loop, since both systems are susceptible to incorrect operation in case of a short circuit of the pilot wire.

As Mr. Rose has stated, the use of an isolated communication system permits the use of the transmitted impulse either to initiate or to prevent tripping. In the case of carrier current the signal must be used to prevent tripping for reasons which have already been explained. Sufficient space was not available in the paper to discuss various possible modifications of the direct-current circuit and it may be well to note here that by making this circuit either of the open or closed type it is possible to arrange either the initiative or preventive methods so that the system will give either, positive operation for faults on the line protected (whether or not the pilot wire circuit is in trouble) at the expense of possible operations on through faults; or positive non-operation on through faults at the expense of possible non-operation for faults on the line. Where it can be used, the initiative method is desirable since it eliminates the necessity for time delay relays. The arrangement to be used is a matter governed largely by the particular installation and involves such factors as the efficiency of the back-up protection provided and the primary purpose for which the protection is installed. That is, if the overall protection is installed merely to speed up the clearing of an otherwise selective system, the arrangement giving positive non-operation on through faults is to be preferred; whereas if the overall protection is installed to obtain selectivity, otherwise impossible, conditions may be such that the failure of the protected line to trip with a fault on it would be far more serious than its tripping on a through fault. In this case positive operation for faults on the protected line would be preferable.

Mr. Rose also has raised a point concerning the interference offered by the communication systems discussed. Since neither the low frequency rectified alternating current pulse system nor the voice frequency telegraph has been applied in the exact manner and for the purpose described, it is impossible to state at this time just how much interference would be offered by these systems. It should be realized that the duration of the interference would be for only a few seconds at very infrequent intervals. Should cases come up where the application of either of these systems appears to be desirable, however, there is little doubt that the interference could be kept within the required limits by the suitable design of the terminal equipment involved.

The methods of protection described are not offered as a panacea for all relay troubles but rather as a useful tool, admittedly costly, which may be the best solution in a great number of situations where the end gained justifies the expense.

Regarding the relative merits of the carrier current and telephone or telegraph circuit systems, the arguments and evidence in favor of either system which have been brought out in the discussions indicate this significant fact—either method is satisfactory and reliable. This is the main thing that we are concerned with here. This paper merely endeavors to indicate the various possibilities in this connection, realizing that the ultimate choice of the system to be used is too largely a matter of local consideration to permit any generalization to be made. With the facilities which are, or can be, made available, this form of protection should go a long way toward solving many of the present difficulties in transmission line relaying.

# Protection of Electrical Apparatus

## Recommended Practise

By Relay Subcommittee,* O. C. Traver, Chairman

**Synopsis.**—*The Relay Subcommittee of the Protective Devices Committee herewith submits its recommendations for the protection of electrical apparatus. These recommendations are based upon a questionnaire and the thirty-seven replies thereto from specialists in this line. The answers were interpreted and codified by a group of twenty experienced engineers particularly interested in the protection of electrical apparatus and circuits. It is hoped that this consensus of the present-day opinion will be the beginning of a series that will be augmented and improved with each periodic analysis and reissue.*

In the past, three papers entitled *Transmission Line Relay Protection* have been presented before the Institute. These indicated the progress of that protective art and discussed in some detail certain methods which were in use at the time they were written.

The last of these, presented in 1930, contained brief notes on the protection of some of the major items of system equipment. It was felt at that time, however, that it would be desirable to have a similar paper presented, devoted entirely to apparatus protection. It is, therefore, the purpose of this paper to present a review of those methods which are in general favor at the present time, and which are considered good practise for the protection of the main items of electrical apparatus.

The information upon which the present paper is based was furnished by representative engineers associated with protective problems in the public utility and industrial fields. In order that the survey might be as comprehensive as possible, 61 copies of a questionnaire were distributed, of which 37 were returned. To guard against answers being given in the light of past practise the transmittal letter laid particular emphasis upon the value of opinions based on future applications rather than upon existing installations. It may therefore be confidently assumed that the condensed results given below express the most advanced ideas of a preponderant body of engineers engaged directly in the study of protective problems.

In a very few cases the average opinion expressed in answers to the questions differs somewhat from the views of the committee. Where such disagreements occur, both opinions are given, together with the reasons which influenced the committee in qualifying the average opinion disclosed by the questionnaire. While agreement was not always unanimous no radically different views were found to exist.

There appears to be a definite recognition of the importance of considering protection problems from two major viewpoints, namely their monetary significance as insurance against damage to equipment, and the less tangible but no less vital relation which they bear to the value of the service in terms of goodwill. The former may readily be computed from existing records of repair costs; the latter is more difficult of evaluation in a pecuniary sense and is consequently susceptible to a variety of conclusions when considered from the angle of return on the capital invested. It is not disputed that this return is large, especially in comparison with the cost of the protective devices, and probably will loom still larger as growth and interconnections continue.

In arriving at its opinions the committee duly weighed the cost of the protective equipment against the value of the results to be expected. This procedure will be found borne out by the kva ratings for which the more expensive methods of protection are recommended. Not only is a large piece of apparatus inherently more costly than a small one but its incapacity to operate due to extensive damage will result in relatively greater inconvenience to the system which it serves.

It should also be remembered that these recommendations apply to the general case and that special situations will arise in which it may be deemed advisable either to raise or lower them. Machines of a certain rating may seem unimportant on a large system and yet attain considerable importance when the system to which they are attached is itself small. In view of the difficulty of basing recommended ratings upon the size of the system the committee felt that it was preferable to consider such ratings upon the more definite basis of intrinsic values and relative costs of protection.

This paper deals particularly with protection against electrical and mechanical failure. When applied to unattended apparatus it overlaps to some extent the field of A.I.E.E. Standards No. 26 on Automatic Stations which also embraces protection against failure of control devices.

### A-C GENERATORS

#### *Whether Steam Turbine, Waterwheel, or Engine-Driven*

*Differential Protection.* In general, differential protection is recommended for a-c generators. This equipment should disconnect the line and field simultaneously and also the neutral if an adequate breaker is provided. In some cases it shuts off the power supply to the prime mover. It should also prevent any dangerous rise of exciter voltage when this machine is directly connected to a hydro-generator or in any other situation in which the exciter may attain excessive speed upon loss of load on the prime mover. As a further precaution against the

---

*For personnel of Relay Subcommittee, see end of paper.

*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

spread of destructive effects following an internal failure, the differential relay may be utilized to liberate carbon dioxide within the shell of any machine which has a degree of enclosure sufficient to render the gas effective.

For generators of either the open or enclosed type at attended stations, differential protection is recommended for ratings of 1,000 kva and above. The average, as derived from the answers to the questionnaire, is 3,000 kva but in view of the intrinsic value and the good results on record the committee felt justified in lowering this figure.

At unattended stations differential protection is recommended for generators rated at 250 kva and above.

From the standpoint of service, a small generator may be frequently as important as a large one, and this is especially true where a small machine is operating directly on a bus with larger generators which are already provided with differential protection. In such a case a fault occurring in the small generator, if not quickly removed, may prove as embarrassing to the service as a similar fault occurring in a large generator; hence differential protection for the small machine is here strongly indicated.

In view of the decreased hazard of insulation failure at low voltages, this form of protection is recommended only on machines rated 2,300 volts and over. This opinion is strengthened by the high current values usually encountered at lower voltages, since these require rather massive terminals and involve greater difficulty in bringing out all the necessary armature leads.

It is recommended that the zone protected by the differential relay include as far as possible all conductors which extend from the generator armature to the bus and the circuit breaker as well.

On generators of 20,000 kva or larger, having two or more parallel windings per phase, and where there is a possibility of turn-to-turn failure, it is recommended that additional protection be provided in the form of a differential relay actuated by a difference of in-phase currents which may occur in the parallel windings. When the neutral is solidly grounded a turn-to-turn fault will usually soon develop into a fault to ground, therefore this protection is recommended particularly in cases where the generator neutral is not solidly grounded. The possibility of circulating currents must also be investigated when parallel balance is contemplated; these however can perhaps be avoided when the machine is designed. Unless this precaution is taken it is possible that circulating currents may cause improper operation of the relay on external faults. With some types of armature windings this relay is also capable of detecting short-circuited turns in the field winding. Since this form of protection is recommended only for large machines its provision adds but a small fraction to the overall cost of the unit.

*Overcurrent Protection.* The use of overcurrent protection for generators in attended stations is not regarded favorably, but at unattended stations it is recommended for back-up protection. When generators at attended or unattended stations are not provided with differential protection, then overcurrent devices, actuated either directly by the armature current or by its thermal effect (replica relay)[1] should be employed. It should be noted however that, because of the rapid decrement of the short-circuit current, care must be exercised in the use of overcurrent relays.

Temperature relays are regarded as a valuable guide to the operator. It is the general opinion that in attended stations they should not disconnect the machine but should only provide a warning signal.

*Field Temperature Protection.* In general field temperature protection is not recommended. An exception however is made in favor of its application to generators which are provided with high-speed excitation and paralleled over long transmission lines. Under short-circuit conditions a heavy field is quickly applied to hold these generators in step. If this field current is not reduced within a reasonable time it is possible that the generator field may overheat without the knowledge of the operator. To guard against this contingency a field temperature relay may be provided to sound an alarm in attended stations and to shut down the unit when the station is unattended.

*Power-Directional Protection with Time Delay.* In the past this combination of protective devices has occasionally been used to prevent motoring on the part of a turbo-driven generator. Since the purpose which it served can now be automatically taken care of at the throttle it is the general opinion that the need for this form of protection no longer exists, except perhaps in rare cases which are not subject to average conditions.

Its use as a protective measure against internal insulation failure is not recommended and can be justified only in the case of old machines which are not provided with sufficient armature terminals for the application of differential protection.

*Bearing Temperature.* Temperature protection is recommended for the main bearings of all unattended machines.

*Protection Against Overspeed.* It is agreed that the usual provision at the prime mover for protection against overspeed is satisfactory for the purpose and that nothing further should be necessary.

*Protection Against Accidental Loss of Field.* Protection against loss of field is recommended for disconnection of the generator at unattended stations. Since a d-c undercurrent relay is the logical device for the purpose it is essential that it be given a suitable time delay to prevent its operation during transients reflected from the armature under short-circuit conditions.

---

1. A replica relay operates at a specific temperature of its own mechanism which is designed to have at all times the same temperature as the device protected when subjected to the same ambient conditions.

Other types of temperature relays function on the actual temperature of the machine as determined by elements in direct contact, such as temperature coils or thermocouples.

In attended stations the relay is seldom used, but when used it should not disconnect the generator but may provide an indication to the operator upon the occurrence of this condition.

### FREQUENCY CONVERTERS AND SYNCHRONOUS CONDENSERS

The same recommendations regarding protective equipment for a-c generators apply also to frequency converters and synchronous condensers. In addition, it is felt that some provision (usually time overcurrent relays) should be made for disconnecting a frequency converter under out-of-step conditions. It is also usually advisable to provide time-delayed undervoltage protection for synchronous condensers. No distinction is made between attended and unattended stations in the use of these additional features.

### D-C GENERATORS

At attended stations protection against overcurrent is considered necessary for the protection of d-c generators, and in addition, when these machines operate in parallel with another source of power, provision should be made for protection against reversal of the normal direction of current flow, functioning independently. Additional refinements are usually necessary in unattended stations but the variety and special nature of these devices do not permit of their inclusion in a general condensed report. Some additional information will be found listed in A.I.E.E. Standards No. 26.

*Bearing Temperature.* Temperature protection is recommended for the main bearings of all unattended machines.

*Exciters.* When the exciters are direct-connected and do not operate in parallel it is recommended that no protection against electrical failure be used. For parallel operation on the other hand protection against overcurrent in a reverse direction should be provided. The current setting should be high enough to prevent possible disconnection of the machines when paralleling and during momentary disturbances reflected from the a-c generator armature under a-c short-circuit conditions.

### POWER TRANSFORMERS AND POWER AUTOTRANSFORMERS

*Differential Protection.*

1. Percentage. When circuit breakers are provided for each winding, percentage differential protection is recommended for two or three winding power transformers of 1,000 kva rating and above, either with or without tap changing equipment, whether operated singly or in parallel. As disclosed by the questionnaire the average minimum was found to be 5,000 kva. The committee interprets this to mean that differential protection should always be provided for banks of 5,000 kva and above, if operated in parallel, even though additional breakers must be purchased.

When the bank is part of a line and provided with a circuit breaker on the bus side only, certain modifications of the foregoing method are recommended. These will be found under a subsequent heading.

When the necessary circuit breakers are provided for complete isolation of a power autotransformer, percentage differential protection is recommended for an equivalent physical capacity of 1,000 kva and above. It is also recommended that all banks of power autotransformers operated in parallel and having an equivalent physical capacity of 5,000 kva and above be provided with differential protection, even though additional breakers must be purchased. The autotransformer output rating corresponding to 1,000 or 5,000 kva of equivalent physical capacity will of course vary with the ratio of voltage transformation.[2]

It is recommended that the circuits embraced by the differential protection include all conductors up to and including the circuit breakers on each side of the transformer.

2. Overcurrent (Differentially-Connected). When differentially-connected overcurrent relays are used in place of percentage differential protection for any of the foregoing types of transformers, it is recommended that they be of the inverse-time type. The time characteristic prevents operation on external faults since these may otherwise create sufficient unbalance at the relay to bring about needless tripping.

*Back-Up Protection.* In addition to differential protection, overcurrent or other back-up protection (not necessarily at the transformer itself) should be provided at some point on the source side to protect the transformer against the effects of sustained excess currents which may arise from the failure of protective apparatus to clear faulty equipment. Temperature relays, either operated by embedded coils or of the replica[1] type, are also occasionally employed.

When a transformer is not protected by differential methods it is always recommended that overcurrent protection be provided.

*Smoke or Gas Detectors.* Insufficient experience in the United States with these devices precludes the expression of an opinion regarding their value, or their possibilities, as a means of transformer protection.

*Transformers Having Breakers in Low Side Only.* Power transformers which have a circuit breaker on the bus side only, the other side being connected directly to the line, are generally treated as part of the line and consequently included in the line protection. When the latter is protected by distance or directional overcurrent relays it is suggested that differential protection also be considered for the power transformer and arranged to trip the transformer breaker. Under some

---

[2] In general the ratio of the equivalent physical capacity of an autotransformer to its kva output is equal to the percent voltage transformation, based on the high voltage thus:

$$\frac{\text{Equivalent capacity}}{\text{Rated output}} = \frac{E_1 - E_2}{E_1} = 1 - \frac{E_2}{E_1}$$

where $E_1$ is the high and $E_2$ the low voltage.

circumstances this will result in speedier isolation of the disturbance. For example, if a fault occurs in the transformer during a period when normal power is flowing from the bus towards the far end of the line, the directional relay at the distant end cannot respond to the fault current until it has grown to proportions sufficient to overcome the torque produced by the normal direction of power. By quickly tripping the bus breaker however the differential relay interrupts the normal flow of power and thus frees the distant directional relay of its normal power torque. It then responds to the lower fault current and the transformer is isolated before serious damage can result.

*Magnetizing Transients.* The replies to the questionnaire disclose that trouble from magnetizing transients is of sufficiently frequent occurrence to warrant some discussion regarding means for overcoming its effect on the protective relays. Inrush magnetizing currents being absorbed within the transformer disturb the balance at the differential relay, and may cause undesirable tripping of the circuit breakers. The ability of sources of large capacity to maintain full voltage on the transformer terminals at the inception of the transient adds greatly to the magnitude which it may attain. These abnormal currents are primarily brought about by the residual flux. Should this be of appreciable magnitude, and in a direction such that the flux change required by the voltage at the moment of closure will push the total flux above the knee of the saturation curve, it follows that the magnetizing current will be unduly large. The difficulty is more pronounced on 25-cycle systems.

Special or additional equipment is available for preventing tripping during the magnetizing transient and this precaution is always necessary when high-speed relays are used. The more common types of relays, however, being slower will usually ride safely through the transient, and where such relays are employed, the committee feels that the addition of the special equipment referred to should be based more properly upon the trouble which the user encounters.

It is also pointed out that undesired operation of differential relays may possibly arise at the moment of clearing an external fault occurring in the vicinity of the transformer. Just before the fault is cleared the voltage at the transformer may have fallen to zero and immediately afterwards will tend to return to normal, thus possibly simulating the conditions obtaining at initial magnetization. Experience of trouble arising from this cause having been meager, the committee does not feel called upon to suggest measures for its avoidance.

## A-C MOTORS

*Differential Protection.* An analysis of the replies to the questionnaire indicates a general agreement on the desirability of differential protection for large a-c motors, the average minimum rating at which it should be applied being 1,750 hp. It was the opinion of the committee that motors of 2,000 hp and above, with a minimum rating of 2,200 volts, should be provided with differential protection.

*Overcurrent Protection.* In addition to differential protection, temperature relays, either of the replica type, or operated by embedded coils, are recommended for protection against excessive or prolonged overloads. Due to loss of cooling by windage the latter may more accurately represent the true temperature of the motor under stalled-rotor conditions.

Below the 2,000 hp rating given above for differential protection it is recommended that motors be provided with inverse-time overcurrent and instantaneous overcurrent protection, the instantaneous relay being set above the stalled-rotor current to take care of severe short circuits without delay.

*Undervoltage Protection.* When undervoltage protection is used it should have sufficient *time delay* to enable the motor to coast through temporary dips in voltage. Undervoltage protection is seldom used for motors which start on full voltage since these will automatically come up to speed when normal voltage is resumed.

*Phase-Rotation Protection.* Phase-rotation relays to guard against reversal of phase-rotation are recommended chiefly for use at unattended stations and in elevator service.

*Protection against Unbalanced Phase Currents.* Dielectric failure results in unbalanced phase currents. This condition may be detected by a relay which is actuated either by the unbalance phase currents themselves or by their corresponding negative phase-sequence components. When differential protection is not possible or practicable these relays are frequently used at unattended stations, but it should be remembered that phase-balancing action will produce unbalanced conditions in sound motors and thus may lead to erroneous tripping on the occasion of an external unbalanced fault.

*Bearing Temperature.* Temperature protection is recommended for the main bearings of all unattended machines.

*Power Station Essential Auxiliary Motors.* It is important that motors driving essential power station auxiliaries be not removed from service except as a last resort, and then in the interest of service, their isolation should be accomplished as promptly as possible. For this reason it is recommended that such motors be protected by instantaneous overcurrent relays set well above the stalled-rotor current. When temperature relays are used in connection with these motors they should be arranged to sound an alarm only. Phase-balance relays or negative phase-sequence relays are not recommended for essential motors because of the phase-balancing tendency of polyphase motors already mentioned under the preceding heading.

It is not common practise to ground the neutral of the supply source for essential motors but if for any reason such a condition exists, then ground relays may be advantageously added to the protection.

### D-C MOTORS

Fuses are considered sufficient protection for small d-c motors. For medium and large sizes, overcurrent and undervoltage protection, usually self-contained in the air circuit breaker itself, are recommended. Where the machine is very large, and its service correspondingly important, additional refinement in the form of temperature protection is desirable.

*Bearing Temperature.* Temperature protection is recommended for the main bearings of all unattended machines.

### SYNCHRONOUS CONVERTERS

Synchronous converters require protection on both the a-c and the d-c sides. On the a-c side inverse-time overcurrent protection is recommended to trip the oil circuit breaker. In addition, when the d-c side is grounded and flashover possible, an instantaneous flashover relay, connected between the machine frame and ground, is recommended to disconnect both the a-c and d-c sides. If the possibility of flashover exists, and no flashover relay is provided, it is recommended that the overcurrent protection on the a-c side be instantaneous instead of inverse-time.

For the d-c side instantaneous overcurrent protection is recommended, and in addition, when the machines are operated in parallel, separate reverse current protection should be provided to disconnect the converter when power flows toward it from the d-c bus. Most synchronous converters are equipped with mechanical overspeed devices: these should trip the d-c circuit breaker and, if the system is subject to runaway speeds, the a-c circuit breaker also.

Additional information will be found listed in the A.I.E.E. Standards No. 26 on Automatic Stations.

*Bearing Temperature.* Temperature protection is recommended for the main bearings of all unattended machines.

### RECTIFIERS

Rectifiers are almost universally automatic in their operation and it is considered that recommendations for their protection are adequately covered by the tabulation given in the A.I.E.E. Standards No. 26 on Automatic Stations.

### BUS PROTECTION

*Differential.* All failures occurring on important buses should be promptly isolated. Differential methods which balance all currents entering and leaving the bus are recommended for this purpose. In such applications it is important that the ratio characteristics of the current transformers in the differential circuit should hold substantially within the relay setting at the maximum primary currents so that incorrect operation cannot occur on external faults. With a given core design, the higher the transformation the more accurate is the ratio curve. The desired conditions can best be achieved by the use of a single ratio for all current transformers taking part in the differential scheme. If it is not possible to follow this recommendation and current transformers of different ratios are employed, then auxiliary current transformers must be used in the secondary circuits to equalize the different ratios at the balance point.

It should be noted, however, that when an auxiliary transformer is used to increase the ratio of a low-ratio line current transformer a double handicap is placed upon the equipment compared to that which would result from the use of a single current transformer having the same total ratio. This follows because:

a. In the lower ratio transformer ratio error begins at lower currents.

b. The additional burden imposed by the auxiliary transformer also has the effect of increasing the ratio error in the line current transformer.

Under certain conditions of power flow, restraint may be advantageously used in the differential relay. In general however these conditions do not obtain, and hence the effect of restraint, if used, cannot be predicted with any degree of certainty.

*Ground Fault Bus.* When the system is grounded, a ground fault bus may be used, each protective relay being operated by a current transformer inserted in the common ground connection for its particular bus section. If provision be made for the application of this method during the station design period, its installation does not involve the serious constructional difficulties that may be encountered in attempting to introduce it in an existing station.

### NEUTRAL GROUNDING EQUIPMENT

*Grounding Resistors and Reactors.* It is recommended that grounding resistors and reactors be protected by overcurrent or temperature relays which, after a short delay sufficient to allow line protection to function, will initiate an alarm to indicate that a ground fault has not been properly cleared. This procedure is designed to give the operator an opportunity to carry out a course of action already decided upon to govern such conditions.

Fortunately the trend toward the use of resistors having a two-minute ground fault capacity allows reasonable time for disconnecting manually the source of the trouble without opening or short-circuiting the resistor. Should either of these latter courses become necessary however it would seem preferable from the protective standpoint to maintain the system ground by short-circuiting the resistor, unless this action nullifies the purpose, such as the prevention of telephone interference, for which the resistor was originally installed.

*Grounding Transformers.* Protection for grounding transformers of either the zig-zag or Y-delta type should follow substantially along the lines indicated for grounding resistors and reactors in so far as the effects of sustained external ground faults are concerned.

For protection against internal faults, two forms of differential protection may be used. In one of these, three differentially-connected overcurrent relays are operated in Y from the delta-connected secondaries of three current transformers located in the line side of the grounding transformers. This is equivalent to differential protection on an ordinary transformer with no load being carried by the secondary, since in the grounding transformer the secondary delta winding carries no external load. It provides protection against both turn-to-turn short-circuit and internal grounds occurring in the transformer, or on the conductors between it and the current transformers.

The other and generally less desirable method compares the zero phase-sequence currents on both sides of the grounding transformer by means of three line current transformers connected in parallel and balanced against a current transformer connected in the neutral. Since turn-to-turn faults do not result in zero phase-sequence currents, this method does not protect against such faults, but functions on faults to ground only.

In applying these forms of protection it is important that the characteristics of the operating current transformers be checked up to maximum short-circuit values.

## IMPRESSIONS

In looking over the preceding recommendations one cannot fail to be impressed by the prominent place still occupied by the simple overcurrent relay in the protection of a wide range of electrical apparatus. Even where it has been supplanted in the first line of defense by more highly selective devices, it is still relied upon as a safeguard of last resort. Nor is this surprising when it is remembered that in any analysis of the destructive effect of dielectric rupture, the major damage is brought about by the thermal, or magnetic effects of high currents. This thought tends to strengthen the belief that the persistence of the overcurrent relay as an important protective agent is destined to extend for a considerable period into the future.

Growing interconnections have brought increasing problems to the operating engineer and his demand for the rapid isolation of faults has brought similar problems to the relay designer. In recent years the trend has been toward the attainment of greater speeds with increased selectivity. Nor is progress in the relay field alone to be recorded; current transformers offering uniform characteristics up to exceptionally high current values are procurable, and circuit breakers capable of interrupting these currents in a brief period of time have been developed.

No discussion on protective methods can be complete without some reference to the primary position taken by the insulation itself. That improvements have been effected in apparatus insulation during recent years cannot be questioned, but there are quite obvious economic factors limiting extension of the insulation to a point of absolute dependability under any and all conditions. Direct lightning is still a thing to be feared and its dangers cannot economically be overcome entirely by increased insulation. Beyond the point at which greater insulation becomes impracticable, the relay must always find its place in the protective economy of the electrical system.

In conclusion the committee desires to extend its thanks to all those who gave so generously of their time in responding to the questionnaire, and without whose collaboration the work of the committee in conducting this survey would have been doubly arduous and its results of considerably less value.

## Discussion

**Philip Sporn:** The Relay Committee has taken in this report a step that has distinct possibilities for a great deal of good in the protection field. The placing before the Institute membership and the entire engineering profession of a complete set of suggested relay practise covering the field of electrical apparatus, together with a discussion of the underlying principles, is bound to stimulate discussion and clarify the basic ideas of relay protection. But, in commending the step it is well to point out the grave danger connected with such a procedure: there is the danger that this may result, or may tend to result, in a codifying of existing practice. In line with this, it may be well for the Relay Subcommittee to re-title its recommendations and call them "Suggested Practice" instead of "Recommended Practice." The distinction between the two may be very fine, but is rather important. It is very important, too, that the Committee avoid setting itself up as an arbiter of what is sound practise, that it avoid in so far as possible a pontifical attitude in a matter that is as flowing and vigorously alive as the relay art. There is no question, for example, that today's relay practise is a tremendous advance over the practise commonly employed a decade ago, but by the same token it must be kept in mind that the relay art of a decade hence will represent in all probability a similar advance over the present art and present practise. All this means, therefore, frequent and careful revision of this report.

Again, it cannot be too strongly emphasized, and the Relay Committee is the logical group to do it, that relay protection is a form of insurance: Insurance of apparatus and insurance of service, and that as insurance, it has to compete against other forms of insurance: and that the premiums represented by the cost of the insurance have to be carefully weighed against the benefits derived. This is but another way of saying that relay protection is in one of its important aspects an economic problem, and only when it is considered as such, are we likely to arrive at the sound engineering basis for good practice.

I cannot help but comment on the Relay Committee's well merited praise of the overcurrent relay. Only, I do not believe that the committee has been strong enough in its statement. It is a fact that the value of the overcurrent relay is recognized today probably to a greater extent than ever before in its history and that it probably occupies today a position in the front line of defense of electrical apparatus and equipment that it has never occupied before. For utmost simplicity and reliability, there is no relay device that gives as much protection for a given expenditure as an overcurrent relay. This in spite of the fact that it almost never can give 100 per cent protection. Properly applied, however, it is a most excellent guardian for the protection of equipment and service.

**O. C. Traver:** The relay subcommittee appreciates the pertinent comments of Mr. Philip Sporn and others who have given attention to this paper.

In presenting its report the committee sought to reflect the best generally accepted practice in relay protection, and certainly did not wish to create an instrument that would impose liability on the part of any operating company that might prefer to follow relay practices other than those described. Therefore the report is, in effect, an outline of "Suggested Practices" and the word "Recommended" in the title must not be taken as imposing a mandate.

Clarification and amplification of another point also seem desirable in the light of the discussion and as a result of further consideration. The paragraph entitled "Undervoltage Protection" has, by subsequent committee action, been entirely superseded by the following:

*Undervoltage Protection.* When undervoltage protection is used it should have sufficient *time delay* to enable the motor to coast through temporary dips in voltage. An exception is made in very rare cases which definitely require immediate action. Induction motors which normally start on full voltage will resume speed without injury to themselves when normal voltage is restored. In such cases undervoltage protection is not required for the motor itself but is frequently necessary to safeguard the operator or the product against unexpected restarting after the motor has once stopped.

# Application of Phase Sequence Principles

## To Relaying of Low-Voltage Secondary Networks

BY H. R. SEARING[1] and R. E. POWERS[2]
Fellow, A.I.E.E Associate, A.I.E.E.

It is the purpose of this paper to present an improved network relaying system utilizing a conventional single-phase relaying element and contactor type overcurrent elements excited by symmetrical phase sequence components to represent completely power flow conditions and control protector operation on a three-phase four-wire secondary network system.

The low-voltage alternating-current network was conceived and developed in order to meet the need for an alternating-current system of distribution that would provide high quality service and compete with the direct-current system in reliability and economy. In its present form, it consists of a distribution network, served by a plurality of feeders, with intermediate voltage transformation and network protectors. The use of the present arrangement dates from the development of the network protector which fulfilled several functions and may be described as a means to connect and disconnect each of the feeders to the network under proper conditions.

The protector consists of a circuit breaker and necessary operating relays located in each of the feeds to the network. Each main feeder provides a multiplicity of feeds to the network through low-capacity transformers, (50 to 1,000 kva) and it is the function of the protector to connect to or disconnect from the feed to the network under proper conditions.

The development of the low-voltage network in metropolitan areas has been very rapid and new problems have continually arisen. The major change in certain localities has been in the supply to the network and has developed from a multiple supply from a single source to multiple supplies from several sources. With the increase in network loading new supplies to the network have been at higher voltage, and voltages of 4, 13, 22, and 27 kv are regularly used. Vertical type building networks of the concentrated or "spot" type are not uncommon.

The principal problem that has arisen from the developments outlined above is that of preventing the excessive number of protector operations that result from power interchanges between feeders through the network. Power reversals, at specific points in any general network under normal operating conditions, are not uncommon and are attributed to:

1. Periodic heavy shunt load drawn from substation buses from which network feeders emanate.
2. Individual feeder loading and induction regulator action.
3. Phase angle and voltage differences in individual generating sources due to loading, etc.
4. Starting of large induction-synchronous motor.
5. Elevator regeneration during braking periods.

Experience has shown that in *certain localities* network protectors when adjusted to trip on reverse magnetizing watts operate at the *rate* of from 10 to 15 thousand times per year per switch as a maximum and that the average number of switch openings are at the rate of from 3 to 5 thousand operations. The number of operations does not indicate incorrect relay performance as the standard unit is designed to operate on small power reversals. This condition causes undue wear on the protector and disconnects a supply source from the network that should be available at all times.

In the practical operation of network systems this duty is reduced by adjusting the relay to trip at increased values of reverse energy; that is, the protector is adjusted so as not to open on the reverse magnetizing watts of a single supply transformer but at some higher value depending upon local conditions. The methods employed to extend the tripping range of a standard network relay (20-30 per cent) ordinarily require additional equipment having moving parts. As the number of protectors with increased reverse power settings becomes large, difficulty is encountered in tripping protectors when the supply breaker is opened. Load-back methods must be resorted to or men sent to the vault or manhole to disconnect protectors.

In an endeavor to produce a network relaying system that would meet the requirements of the original relay specifications and in addition be sufficiently broad in its characteristics to permit the flow of reverse energy encountered in normal operation, phase sequence currents and voltages have been utilized in a new network relaying system. These single-phase symmetrical components of current and voltage replace the three line-to-neutral voltages and phase currents ordinarily used and completely indicate power flow conditions. The preliminary mathematical analysis, subsequent relay design and field tests have proved the correctness of the theory and application, and indicates the practicability of utilizing sequence components in relaying systems producing a simplification of apparatus with improved characteristics.

Symmetrical component quantities may be considered as the mathematician's conception of a polyphase system, however, the quantities concerned are real, not imaginary, and are amenable to actual measurement. Through the work of Fortescue, Evans, Wagner and others, phase sequence segregating filters have been developed permitting the isolation of any or all of the phase sequence currents and voltages, which may be applied to conventional elements to secure metering or relaying functions in response to changes in sequence quantities.

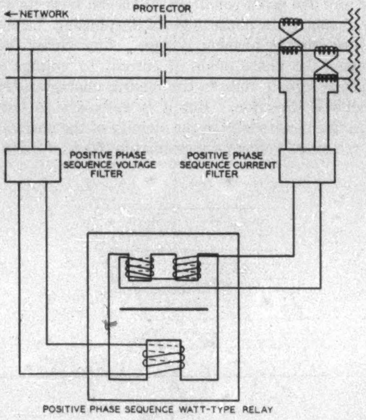
*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

A review of network relay requirements, embracing application to systems employing low- and high-voltage feeders from segregated substations and generating sources, feeding into a general network supplemented by spot networks, indicate the necessity for:

1. A master directional element to indicate direction of power flow.
2. Phasing features to control protector closing.
3. Selective tripping features in the relaying system to prevent opening of the protector upon reversal of energy through the switch during normal system operation with the feeder breaker connected to the source.
4. Sensitive tripping when the feeder is disconnected by the opening of the generating or substation breaker.



←NETWORK
PROTECTOR
POSITIVE PHASE SEQUENCE VOLTAGE FILTER
POSITIVE PHASE SEQUENCE CURRENT FILTER
POSITIVE PHASE SEQUENCE WATT-TYPE RELAY

Fig. 1

These requirements are fulfilled by the new relay system.

The master directional element consists of a single-phase watt relay operating on positive phase sequence voltage and current. This element is responsive to the direction of flow of positive phase sequence power under all conditions (Fig. 1).

To be generally satisfactory from the standpoint of performing the phasing features the relay must

1. Check phase sequence.
2. Check any interchange of phase wires on the supply feeder.
3. Connect the protector to the grid only when power will be fed from the feeder into the network.
4. Prevent any "pumping" of protectors, when the supply breaker is open and a defective unit remains in the closed position, thus energizing the feeder from the network.
5. Permit closing on a dead network.

Phasing is accomplished in the new relay by the use of voltage segregating filters and auxiliary windings on the watt relay used as a master directional element.

A voltage segregating filter of the positive phase sequence type when connected to a system of phase sequence *abc* delivers at its output terminals a voltage proportional, under all conditions, to the positive phase sequence voltage. If the supply voltage is balanced, the output of the network will be proportional to and bear a definite phase relationship to the line to neutral voltage. If for any reason, two phases are interchanged the supply system phase sequence, (order of appearance of maxima) is changed from *abc* to *acb* and when impressed on a sequence segregating voltage filter designed to deliver positive phase sequence voltage with normal phase sequence *abc* the output of the network will be zero, if the supply is balanced. During phasing periods experience and test have shown that balanced voltage conditions exist on incoming feeder circuits although phase sequence may be incorrect. Certain progressive interchange of leads on the supply circuit gives rise to proper phase sequence *abc* but rotated 120 deg or 240 deg in the counter-clockwise direction with respect to normal network voltage. Under this condition the output of the network is normal but rotated 120 deg or 240 deg respectively.

The fundamental characteristics of voltage sequence segregating filters in response to changes in phase sequence, polarity reversals, and phase advancement discloses the possibility of using phase sequence quantities to accomplish phasing functions. Obviously, single-phase representation of the selected quantity may be employed thus permitting the use of a single-phase relay to adequately represent a polyphase system.

Drawing on the experience gained with the present protector relaying scheme, it has been demonstrated that the phasing characteristics can be secured by adding to the upper or current poles of the watt type relay phasing windings excited by voltage across the open switch. The potential or lower pole of the relay is excited by voltage from the secondary network. The network voltage is chosen as reference point as it is necessary to check the incoming feeder in magnitude, phase position and sequence against that of the network to insure proper operation.

Following the conventional design of relay element "watt" and "phasing" characteristics can be secured on a single-element relay (see Fig. 2) by the use of

1. Positive phase sequence voltage and current for watt indication.

2. Network positive phase sequence voltage and the difference between network positive phase sequence voltage and incoming feeder positive phase sequence voltage (difference positive phase sequence voltage across the open protector) to perform phasing functions.

The combined phasing characteristic of the present *CN*-3 master relay and the *CNA* phasing relay is shown in Fig. 3, indicating that protector closure can occur only in a rather limited range due to the combined phasing features of both relays.

POSITIVE PHASE SEQUENCE OVERCURRENT RELAY
WATT AND PHASING ELEMENT

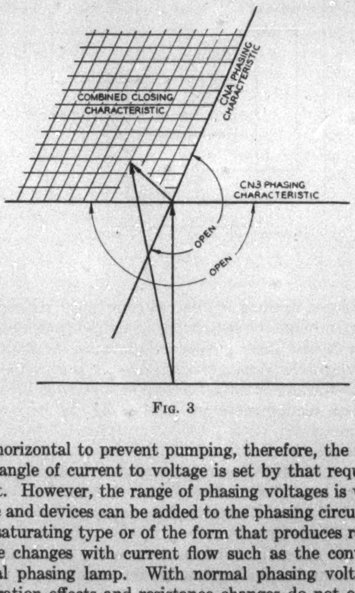
Fig. 2

In utilizing phase sequence quantities to develop a relay with settings, 10-100 per cent of transformer rating, it is not necessary to confine the "closing region" to the limited range employed in the present standard equipment but may be extended to embrace *leading* voltages lower in magnitude than the network voltage. In actual practise these voltages occur very infrequently as incoming feeder voltage is high and leading, not low and leading.

To prevent "pumping" of protectors on systems employing high-voltage underground feeders the phasing characteristics must be such that the relay contacts will not close when the incoming voltage is high and lagging indicating a "closed" protector exciting the capacitance of the cable from the network, with consequent voltage rise across the secondary mesh and network transformer. Mathematical analysis, field tests and a check on the performance of existing relays indicate that to avoid pumping conditions the closing characteristic of the network relay as a phasing device, must be rotated through approximately 60 to 70 deg from the horizontal, as shown in Fig. 4. While linear closing characteristic of this nature would be excellent for a non-sensitive type relay, a study of Fig. 4 will show that the linear characteristic intersects the voltage $Ec_1$ and would permit protector closure due to cyclic rotation of conductors that produced normal phase sequence *abc* but advanced counter-clockwise 120 deg with respect to the reference or secondary network voltage.

The phasing voltages encountered in normal system operation are relatively small, having a magnitude of only a few volts. Under the conditions outlined above, the phasing voltage would approximate in magnitude the line-to-line voltages $E_p$, Fig. 4, which is many times the normal phasing voltage. It is desirable to have the phasing characteristic linear in the range of normal phasing voltages, but to deviate therefrom at higher values so as to avoid possible improper operation, under certain system conditions that are a function of system repair and extension involving the human element.

It is recognized that the slope of the closing characteristic may be changed by governing the relationships between the flux on the upper and lower pole of the relay, for any one given condition. This can be accomplished by changing the phase angle of the phasing current with respect to the phasing voltage. Any factor that decreases the phase angle of current to voltage in the phasing circuit rotates the closing characteristic in a clockwise direction. But it is necessary to have the closing characteristic in the vicinity of the normal value of reference voltage approximately 60 to 70 deg from the horizontal to prevent pumping, therefore, the normal angle of current to voltage is set by that requirement. However, the range of phasing voltages is very large and devices can be added to the phasing circuit of the saturating type or of the form that produces resistance changes with current flow such as the conventional phasing lamp. With normal phasing voltages saturation effects and resistance changes do not occur and the phasing characteristic is linear. With increasing phasing voltages these changes occur and the ratio of



COMBINED CLOSING CHARACTERISTIC
CNA PHASING CHARACTERISTIC
CN3 PHASING CHARACTERISTIC
OPEN
OPEN

Fig. 3

reactance to resistance varies, resulting in change in the angle between phasing coil currents and voltage, causing a deviation from a straight line in the phasing characteristic as shown dotted in Fig. 4. The changing characteristics of the phasing circuit, with increased phasing voltages must be such that the characteristic curve does not intersect a voltage vector of normal magnitude rotated 120 deg counter-clockwise to prevent false closure in event of accidental cyclic rotation of conductors during cable splicing producing a 120 deg shift of positive phase sequence voltage. The changing characteristics on the upper part of the phasing curve encroaches upon the possible range of back feed voltages existing due to a single "closed" protector on systems supplied by underground high voltage cables. Analytical work and field tests indicate that the proposed curve is sufficiently broad in its characteristics to perform satisfactorily on existing and proposed systems employing 13- and 27-kv feeder circuits.

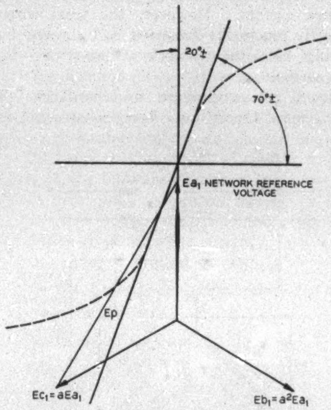


FIG. 4

Selective and sensitive tripping is obtained by the combined operation of the master directional element and current magnitude relays. Selective tripping refers to relay operation with balanced reverse power flow and would be above the range produced by the inherent system conditions during normal operations. This feature reproduces the results obtained from present network relays when increased reverse power settings are used.

The current magnitude relay used for selective tripping is a simple single-phase contractor type relay energized by positive phase sequence current. When positive phase sequence current of sufficient magnitude has closed the contacts of this relay, the potential coil of the master directional relay is energized and tripping of the protector occurs if the power flow is from the network to the feeder.

Sensitive tripping refers to relay operation at times when the supply breaker is open. A current magnitude relay energized by the negative phase sequence component of the line current and operating in a manner similar to the relay used for selective tripping, provides for sensitive tripping.

A current segregating filter provides the symmetrical components of line current.

Negative phase sequence current does not exist in a perfectly balanced polyphase system. In the practical low-voltage network system under normal operation negative phase sequence current exists only in very minor quantities. However, every unbalanced load or fault acts as a source of negative phase sequence voltage and current transforming or converting from positive phase to negative phase sequence order. The same considerations apply to zero sequence quantities if the system or mesh is grounded. We thus have a quantity which is absent normally but is available under abnormal conditions to provide a discriminating means whereby tripping functions may be initiated.

Therefore, if the selective tripping combination is supplemented by a negative phase sequence overcurrent relay, tripping of the protector can be limited to fault or reverse unbalance conditions on the high-tension feeder.

The appearance of negative phase sequence current, at a time when positive phase sequence power is from the grid to the feeder indicates abnormal conditions such as a primary fault or primary load unbalance and warrants protector opening. The negative phase sequence current element can be set at low values since only small quantities of negative phase sequence current are normally present in the system.

Since the sensitive tripping arrangement provides for clearing the protector in case of faults, it would appear that the selective tripping feature is unnecessary except for the condition of a three-phase balanced feeder fault or to avoid damage to individual protectors from overloading during abnormal system conditions not identified with any particular feeder. Field experience may show that the selective tripping arrangement can be eliminated.

While tripping functions are, therefore, provided for all types of primary faults and eliminated for all secondary faults, provision must be made for clearing of the protectors for inspection or construction purposes.

This is accomplished by providing a source of negative phase sequence current. A small induction-synchronous motor-generator set arranged as in Fig. 5 and connected to the feeder at the generating source after opening the feeder breaker may be used. The voltage required will be relatively low as only small values of negative phase sequence current are required and the impedance to the flow of negative phase sequence current is the short circuit impedance of the negative phase sequence mesh. Thus the kva capacity of equipment required and the current flow during operation will be so low that voltage disturbance will not result on the secondary network.

In stations equipped with ground and test bus, the motor-generator set can be connected to it through suitable transformers and without starting apparatus.

The majority of transformers used in network distribution are delta connected on the primary winding, and the neutral of the feeder circuit usually is established at the generating station. Upon opening of the feeder breaker the feeder circuit is ungrounded and negative phase sequence current can be produced by earthing one conductor of the delta-connected circuit which effectively short-circuits out the capacitance of that conductor and increases the voltage on the capacitance to ground of the other conductors. This is equivalent to loading of two phases only, thus creating a load unbalance and giving rise to negative sequence current. The magnitude of current will depend upon capacitance and thus upon the type, length and voltage of the circuit involved. Higher-voltage underground cable circuits, 13 kv and above, will be most effective in producing negative sequence current when one conductor is earthed.

a
NEGATIVE PHASE SEQUENCE GENERATOR
DRIVING MOTOR

Fig. 5

Any type of apparatus that places an unbalanced load between phases produces negative sequence current and any simple loading device can be employed. Phase-to-phase loading is preferable to phase-to-ground loading.

Apparatus for the generation of negative phase sequence current may be located in the high-tension circuit at the generating station or in the low-voltage network on the transformer side of a single protector per feeder.

As pointed out previously, negative phase sequence current of appreciable magnitude is normally not present in the system, but does appear under fault conditions or unbalance. Therefore, negative phase sequence current offers a ready means to discriminate between normal and abnormal circuit conditions.

It is interesting to note that phase angle or balanced difference voltage between various points in the network produce circulating currents of positive sequence order. In the practical system, operating experience and field test indicate that the so-called circulatory currents are predominately positive phase sequence and contain only negligible components of negative phase sequence currents. This current is produced by phase angle and voltage difference in the three phases of the system due to slight unbalance in phase loading. Individual load unbalance, single-phase line-to-line or line-to-neutral load in the secondary network produces negative phase sequence current. However, the total three-phase loading is practically balanced as indicated by commercially balanced network voltages and balanced feeder currents.

Network relays designed in accordance with the above general theory have been constructed and are now in operation on the system of the United Electric Light and Power Company in New York where approximately 400 relay months of service has been secured. The satisfactory performance of the relays in the most severe type of service that could be selected within the system, indicate the adequacy of the fundamental principles and subsequent relay design. The general features of relay design and operating experience will be outlined in a companion paper by Messrs. M. A. Bostwick and H. S. Orcutt.

Fig. 6—Combination Current Filter to Indicate Positive and Negative Phase Sequence Current

It is our desire to express appreciation for the assistance given by Dr. C. L. Fortescue, C. F. Wagner, R. D. Evans, G. R. Milne and W. A. Lewis in analyzing and applying phase sequence principles to the relaying system used in low-voltage networks.

## Appendix 1

### COMBINATION SEQUENCE SEGREGATING FILTER DESIGNED TO DELIVER SIMULTANEOUSLY POSITIVE AND NEGATIVE SEQUENCE CURRENT

The determination of a given phase sequence current requires that the remaining two current components be eliminated, that is not passed through the meter element. In three-phase ungrounded operation, zero phase sequence currents are not present and are automatically eliminated. In grounded neutral systems zero phase sequence current is present and means must be provided to eliminate the possibility of its appearance in the relay element.

*Elimination of Zero Sequence Currents.* Fundamentally, zero sequence currents in the three line conductors are equal and in phase. If cross-connected current transformers are used, as shown in Fig. 6, for the supply to a sequence segregating filter the output of the two current transformers will not contain zero sequence currents. Inasmuch as the output of the two current transformers is the difference between the two-phase currents the zero phase sequence current is automatically cancelled and the output contains only positive and negative phase sequence current.

In Fig. 6, following recognized convention

$$IA' = Ic - Ib = aIa_1 + a^2Ia_2 + Ia_0 - a^2Ia_1 - aIa_2 - Ia_0$$

$$= (a - a^2)(Ia_1 - Ia_2) = J\sqrt{3}\,(Ia_1 - Ia_2) \qquad (1)$$

$$IC' = Ib - Ia = a^2Ia_1 + aIa_2 + Ia_0 - Ia_1 - Ia_2 - Ia_0$$

$$= (a^2 - 1)\,Ia_1 + (a - 1)\,Ia_2$$

$$= \sqrt{3}\,e^{j210}\,Ia_1 + \sqrt{3}\,e^{j150}\,Ia_2$$

$$= J\sqrt{3}\,(aIa - a^2Ia_2) \qquad (2)$$

From equations (**1**) and (**2**) it is seen that the positive and negative phase sequence currents in $IA'$ and $IC'$ are directly proportional to the corresponding components of $Ia$ and $Ic$

$$IA_1' = J\sqrt{3}\,Ia_1 \qquad (3)$$

$$IA_2' = -J\sqrt{3}\,Ia_2 \qquad (4)$$

With elimination of the zero phase sequence component of current by the use of cross connected current transformer

$$IA_o' = 1/3\,(IA' + IB + IC') = 0 \qquad (5)$$

$$IB' = -(IA' + IC') \qquad (6)$$

by definition

$$IA_1' = 1/3\,(IA' + aIB' + a^2IC') \qquad (7)$$

Substituting (**6**) in (**7**)

$$IA'_1 = 1/3\,(IA' - IA' - IC' + a^2IC')$$

$$= 1/3\,(1 - a)\,IA' + (a^2 - a)\,IC'$$

$$= 1/3\,(\sqrt{3}\,e^{-j30}\,IA' + \sqrt{3}\,e^{-j90}\,IC')$$

$$= J\frac{\sqrt{3}}{3}\,(e^{-j120}\,IA' + c^{-j180}\,IC')$$

$$= J\frac{\sqrt{3}}{3}\,(a^2IA' - IC') \qquad (8)$$

Equation (**8**) may be written

$$IA_1' = \frac{\sqrt{3}}{3}\,e^{j300}\,(IA'\,e^{j30} + IC'\,e^{-j30}) \qquad (9)$$

$$= e^{-j60}\left(\frac{\sqrt{3}}{3}\,IA'\,e^{j30} + \frac{\sqrt{3}}{3}\,IC'\,c^{-j30}\right) \qquad (10)$$

$$Ia_1 = -J\,\frac{IA'}{\sqrt{3}} \text{ from equation (3)} \qquad (11)$$

$$Ia_1 = \frac{-J}{\sqrt{3}}\,e^{-j60}\left(\frac{\sqrt{3}}{3}\,IA'\,e^{j30} + \frac{\sqrt{3}}{3}\,IC'\,e^{-j30}\right) \qquad (12)$$

$$Ia_1 = \frac{1}{\sqrt{3}}\,e^{-j150}\left(\frac{\sqrt{3}}{3}IA'\,e^{+j30} + \frac{\sqrt{3}}{3}\,IC'\,e^{-j30}\right) \qquad (13)$$

$$Im_{a1} = \left(\frac{\sqrt{3}}{3}\,IA' + \frac{\sqrt{3}}{3}\,IC'\right) = \sqrt{3}\,Ia_1e^{j150} \qquad (14)$$

or

$$-Im = \sqrt{3}\,Ia_1\,e^{-j30} \qquad (15)$$

by similar development

$$Ia_2 = \frac{1}{\sqrt{3}}\,e^{j150}\left(\frac{\sqrt{3}}{3}\,IA'C^{-j30} + \frac{\sqrt{3}}{3}IC'\,e^{+j30}\right) \qquad (16)$$

$$Im_{a2} = \left(\frac{\sqrt{3}}{3}\,IA'e^{-j30} + \frac{\sqrt{3}}{3}\,IC'\,e^{j30}\right)$$

$$= \sqrt{3}\,Ia_2\,e^{-j150} \qquad (17)$$

or

$$-Ima_2 = \sqrt{3}\,Ia_2\,e^{+j30} \qquad (18)$$

From equations (**13**) and (**16**) it will be seen that a current proportional to positive or negative phase sequence current can be secured by adding suitable components of current $IA'$ and $IC'$ and passing the resultant through a suitable metering element. Inasmuch as only fractional portions of the $A'$ and $C'$ currents are added to produce either positive or negative phase sequence currents it is obvious that parallel branch or bridge type filters are required. Such a filter is shown in Fig. 6. To secure the proper subdivision of the $IA'$ and $IC'$ currents the elements in the current filter must be properly coordinated.

$$Zp = Zn$$

$$Zz + Zn = (R + Zp)\,e^{j60}$$

Considering only the $IA'$ current flowing in the filter, the current divides, a component $\frac{\sqrt{3}}{3}\, IA'\, e^{j30}$ flows through $R$ and $P$. The remainder $\frac{\sqrt{3}}{3}\, IA'\, e^{-j30}$ flows through $Z$ and $N$.

Considering only the current flow $IC'$ a component $\frac{\sqrt{3}}{3}\, IC'\, e^{-j30}$ flows in $P$ and $Z$, the remainder $\frac{\sqrt{3}}{3}\, IC'\, e^{j30}$ flows in $R$ and $N$.

The resultant current flow in

$$P = \left( \frac{\sqrt{3}}{3}\, IA'\, e^{j30} + \frac{\sqrt{3}}{3}\, IC'\, e^{-j30} \right) = \sqrt{3}\; Ia_1\; e^{j150}$$

The resultant current flow in

$$N = \left( \frac{\sqrt{3}}{3}\, IA'\, e^{-j30} + \frac{\sqrt{3}}{3}\, IC'\, e^{+j30} \right) = \sqrt{3}\, Ia_2\, e^{-j150}$$

A filter is thus produced that permits simultaneous indication of currents proportional to positive and negative sequence currents in the leads of the supply circuits. Zero phase sequence current being eliminated by the use of cross connected current transformers.

The elements $P$ and $N$ may be any form of relaying or indicating apparatus providing the fundamental relationship of $Z_s + Z_n = (R + Z_p)\, e^{j60}$ is maintained.

The magnitude of positive or negative phase sequence current indicated in branches $P$ and $N$ respectively is $\sqrt{3}$ times the actual sequence component in the line conductor and is displaced by 150 or 30 deg depending upon physical connections. In relaying or metering circuits both magnitude and angular relationship must be properly related to secure proper indications.

## Discussion

For discussion of this paper see page 626.

# A Sequence Relay for Network Protectors

BY H. S. ORCUTT* and M. A. BOSTWICK†
Associate, A.I.E.E. Non-member

PROTECTORS on many low-voltage distribution networks of today operate needlessly several thousands of times each year due to current reversals caused by regenerative loads and difference in loading at various points in the network. Such reversals can be permitted without tripping the protectors and yet maintain a desirable selective tripping characteristic by use of a phase sequence scheme of relaying devised by Messrs. H. R. Searing and R. E. Powers. It employs the fact that practically all power reversals, other than fault conditions, are inherently balanced and that operation of a directional relay can be easily initiated by simple switching operations which draw negative phase sequence currents from the network.

The sequence relay which has been designed in accordance with their theory, and described in this paper, performs the dual function of phasing and tripping. Its operating characteristics, as shown in Fig. 1, are suited to application on low-voltage distribution systems in general.

## CONSTRUCTION

Structurally the sequence relay consists of a single induction-disk directional element, and two over-current elements energized through suitable current and voltage filters. The relay, with the exception of two resistors and a phasing lamp, is mounted within a standard network relay case as shown in Fig. 2. The schematic diagram, Fig. 3, indicates the various elements of the relay and the circuits employed. The control circuit, which is not shown, is energized through contacts on the directional element.

## POTENTIAL FILTER

The potential filter consists of an autotransformer and a reactor, mounted in the base of the relay, and an external resistor. Composite diagrams, Figs. 4, 5 and 6, illustrate the operation of this filter under balanced and unbalanced conditions, and show that the relay voltage obtained is proportional to the positive phase sequence voltage of the system and removed from it by a constant angle.

The reactor-resistor combination, connected across $E_C$ in Figs. 4, 5 and 6, has an impedance angle of 60 deg. The autotransformer is tapped at approximately its midpoint. It will be noted that the open circuit relay voltage obtained, $E_R$, is equal to the vector sum of the voltage rise through the resistor and the induced voltage in the autotransformer. It is proportional to the positive phase sequence voltage $E_{a1}$ of the distribution network and leads it by 120 deg.

The magnitude of the open-circuit relay voltage $E_R$ is determined by the ratio $(N)$ of the external resistance to the sum of the external resistance plus the a-c resistance of the reactor.

$$N = \frac{R}{R + r} \qquad E_R = N\sqrt{3}\,\frac{E_{A1}}{2}$$

$R$ = external resistance
$r$ = a-c resistance of the reactor.

The current in the potential circuit will lag the open-circuit potential coil voltage by an angle that is a function of the series impedance of the potential coil and voltage filter.

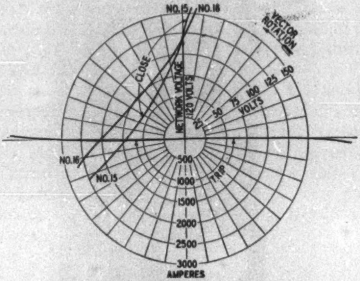

FIG. 1—OPERATING CHARACTERISTICS OF TYPE CN-S NETWORK RELAY STYLE N630355. SERIAL1171632

Assuming balanced three-phase conditions 1,600-ampere current transformers 1,600-5 ratio

$Z_F$ = equivalent impedance of voltage filter

$$Z_F = \frac{R}{4}\,(4 - N + j\sqrt{3}N)$$

For accurate measurements of positive phase sequence voltages the resistance of the autotransformer winding must be kept relatively small.

## CURRENT FILTER

The current filter illustrated in Fig. 7 consists of the current coil of the directional element and a contactor type positive phase sequence current relay connected in series $Z_1$, a reactor $Z_2$ and a negative phase sequence current relay of contactor type $Z_3$, all mounted within the main relay case. An external resistor $Z_4$ completes the bridge type filter. Four current transformers, cross connected, in Fig. 3, to eliminate zero phase sequence currents from the relay, are used to energize the current

filter. Vector diagrams in Figs. 8, 9 and 10 indicate its operation under various conditions.

The currents $I_C'$ and $I_A'$ from the cross-connected current transformers pass through the current filter as indicated in Fig. 7. Current $I_C'$ divides into equal parts ($I_W$ and $I_X$) separated by a phase angle of 60 deg as shown in Figs. 8, 9 and 10. Current $I_A'$ divides in a similar manner into $I_Y$ and $I_Z$.

The positive phase sequence vector diagram illustrated in Fig. 8, shows the currents through $Z_1$ ($I_X$ and $I_Y$) adding to give a positive phase sequence relay current $I_R$ equal to the $\sqrt{3}$ times the positive phase sequence current of the distribution network and leading it by 150 deg. The currents through the negative phase sequence relay $Z_2$, ($I_W$ and $I_Z$) are equal and opposite and therefore cancel.

Fig. 2

In the negative phase sequence diagram, Fig. 9 which illustrates conditions obtained when phases $B$ and $C$ are interchanged, the current vectors $I_X$ and $I_Y$ which pass through the positive phase sequence relay cancel. Current vectors $I_W$ and $I_Z$ which pass through the negative phase sequence relay add up to equal the $\sqrt{3}$ times the negative phase sequence current of the system.

Inspection of the unbalanced current vectors in Fig. 10 again show the positive phase sequence relay current to be the $\sqrt{3}$ times the positive phase sequence current in the system and leading it by 150 deg. The negative phase sequence current present in the system condition illustrated is also shown. As only positive phase sequence current is used in the directional element of the relay, we are not interested in the phase position of the negative phase sequence current.

Addition of current and voltage vectors representing these unbalanced systems, chosen at random, indicate, as has been proven mathematically in other papers, that these filters will produce currents and voltages that are proportional to the positive or negative phase sequence quantities existing in the system from which they are energized. The series impedance of the voltage filter and potential coil is designed so that these elements can be combined to obtain the sensitive watt characteristic needed in the directional element.

The dual sensitive, non-sensitive relay characteristic is obtained by the combined operation of the directional element and over-current elements. Parallel connection of the positive and negative phase sequence current element contacts in the potential coil circuit serve to deenergize the potential coil during normal conditions. Operation of the directional element for the tripping function is initiated by action of either or both of the over-current elements. A short time delay is obtained between closure of the current element and directional element contacts, since this contact is held open by spring tension. This interval need be no greater than the operating time of present network relays, yet serves

to prevent tripping the protector by sudden applications of load on the secondary network.

By setting the positive phase sequence element to pick up at currents up to 100 per cent of protector rating, balanced power reversals of that magnitude can be permitted. Negative phase sequence current settings are made relatively low so that sensitive operation of the directional element can be initiated by small magnitudes of negative phase sequence current.

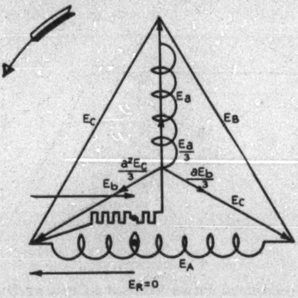

Fig. 5—Negative Phase Sequence Voltage Diagram

It is of importance to note that sensitive operation of this relay may be obtained at all times by permanently closing the contacts of either or both current elements, if the insensitive reverse current characteristic is not needed and a negative phase sequence current source is not readily available. When this is done, the relay functions as a sensitive positive phase sequence directional element and can be used to replace the present sensitive relay.

In order to obtain a clear picture of the relay operation, it may be assumed that balanced three-phase power is being fed in the reverse direction through the protector. All pallet switches in Fig. 3 are open since the protector is closed. The potential coil of the directional element is deenergized and the relay trip contacts are held open by spring tension, as negative phase sequence current is not present and the positive phase sequence current is not of sufficient magnitude to close the current element contacts. Now assume an assymetrical fault in the network, similar to that shown in Figs. 6 and 10. The moment the fault occurs, positive and negative phase sequence currents appear in sufficient magnitude to close the sequence element contacts, energizing the potential coil. Since the fault is in the network the directional element tends to swing its contacts toward the closed position and tripping of the protector is thus prevented. Had the fault occurred in the feeder cables, operation would have been the same except the relay contacts would have swung from the closed to the trip position and opened the protector.

## Phasing Circuit

The phasing characteristic illustrated in Fig. 1 will prevent pumping of non-sensitive relays on low-voltage distribution networks and is sufficiently limiting in its operating range to be satisfactory for many sensitive relay applications. In addition to checking the magnitude and phase position of the feeder voltage, the relay will not close if any of the feeder cables are interchanged and energized.

The phasing circuit consists of two separate coils of high impedance mounted separately over the directional element current coils. One coil is connected in series with a saturating reactor and capacitor, across the breaker contacts in phase *B*. This circuit is near resonance during normal conditions to provide ample torque for low phasing voltages. The second coil is connected across the phase *C* breaker contacts in series with a tapped reactor and a phasing lamp. The phase angles of these circuits are such that the currents in the two circuits are approximately 180 deg out of phase under normal voltage conditions. The resulting field of flux is as in a conventional circuit. When excited with high voltages, as encountered during cross phase conditions, the impedances increase to limit the current and phase angles change so as to obtain opening torque and prevent damaging the protector by faulty closing. Vector diagram, Fig. 11, illustrates the operation of this circuit.

The tap on the phase *C* reactor serves to shift the relay closing curve, as indicated in Fig. 1, to prevent pumping if the system impedance angle will not permit use of the lagging closing curve.

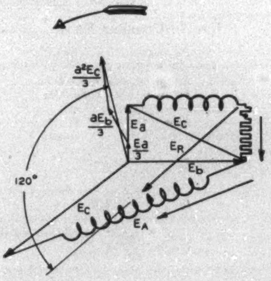

Fig. 6—Unbalanced Voltage Diagram

## Operating Experience

Ten experimental relays, with the current element contacts connected directly in the trip circuit rather than in the potential coil circuit as just described, were mounted on 500-ampere network protectors and installed on a 13.8-kv feeder of the United Electric Light & Power Company's system, April 11, 1931. All transformer banks connected to the feeder, which was 2.8 miles long, were of 150-kva rated capacity.

A general comparison of the operations of network protectors equipped with these sequence relays with the operations of protectors equipped with standard insensitive network relays installed previously at the same locations showed that the operations were reduced on the average only 40 per cent.

On blocking open the negative phase sequence current element contacts, it was found that further reductions in operations on the average of 90 per cent were obtained. The settings of negative phase sequence current elements were subsequently increased from 5 per cent of the protector rating to 8 per cent. The positive phase sequence current element setting at 50 per cent of the protector rating was not changed. While an improvement in the operation of the relays was affected, the results were not satisfactory.

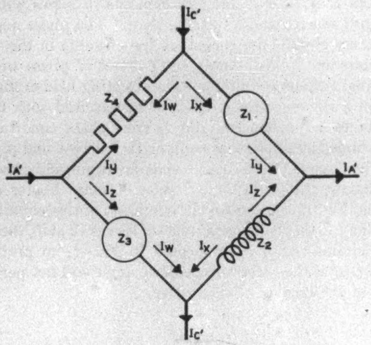

FIG. 7—CURRENT FILTER

$$Z_1 = Z_3$$
$$Z_1 + Z_4 = (Z_2 + Z_3)\epsilon^{-j60}$$
$$I_{C'} = Ib - Ia = Iw + Ix$$
$$I_{A'} = Ic - Ib = Iy + Iz$$
$$Iw = \frac{I_{C'}}{\sqrt{3}}\epsilon^{j30}$$
$$\left.\begin{matrix} Ia \\ Ib \\ Ic \end{matrix}\right\} = \text{Line currents}$$
$$Ix = \frac{I_{C'}}{\sqrt{3}}\epsilon^{-j30}$$
$$Iy = \frac{I_{A'}}{\sqrt{3}}\epsilon^{j30}$$
$$Iz = \frac{I_{A'}}{\sqrt{3}}\epsilon^{-j30}$$

From observations made, it was found that the current elements were causing the protectors to trip on suddenly applied secondary loads when the directional element trip contacts were held closed by power reversals. It should be remembered that the contacts of the current elements, in these experimental relays, were in series with the "trip" contacts of the directional element. Thus on the occurrence of an unbalanced secondary load, the negative phase sequence current element picked up, and since the directional element "trip" contacts were closed by the reverse power flow, the protector opened. The current elements, which are practically instantaneous, picked up before the directional element, which tended to close on the secondary load had time to open its "trip" contacts, thus completed the trip circuit. Large unbalanced secondary loads suddenly applied produced similar operations with the positive phase sequence current element picking up.

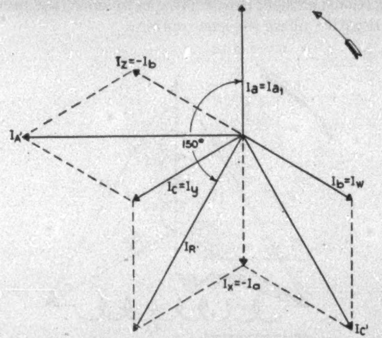

FIG. 8—POSITIVE PHASE SEQUENCE CURRENT DIAGRAM

$$I_R = Iy + Ix = \sqrt{3}\, Ia_1\, \epsilon^{j150}$$
$$I_N = Ia_2 = Iw + Iz = 0$$

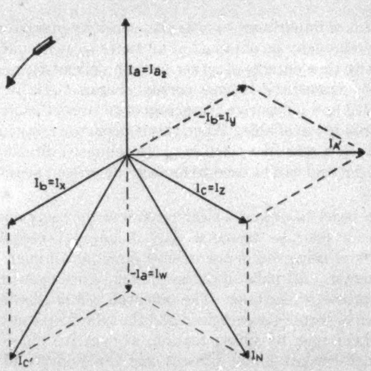

FIG. 9—NEGATIVE PHASE SEQUENCE CURRENT DIAGRAM

$$I_N = Iz + Iw = \sqrt{3}\, Ia_2\, \epsilon^{-j150}$$
$$I_R = Ix + Iy = 0$$

To remedy this condition, the contacts of the current elements of the ten sequence relays were connected in series with the potential coil of the directional element as shown in Fig. 3. With this arrangement, the directional element "trip" contacts were normally opened and thus when either of the current elements picked up on a secondary load, the "trip" circuit could not be completed, as the disk of the directional element tended to rotate further in the "close" direction.

The network protectors equipped with these experimental sequence relays have been used at several other locations, since their initial installation, in order to obtain operating experience under all possible system conditions. Locations were selected where frequent and large reversals of power occurred due to elevator regeneration or other conditions. Satisfactory operation of all protectors was experienced at every location.

The operating record of the protectors now in service is tabulated below. The list includes all operations due to cable faults, interruption of the feeder at its source, and power reversals in excess of relay settings.

| Feeder voltage (kv) | Period (days) | Total operations for period | Average operations per day |
|---|---|---|---|
| 13.8 | 262 | 21 | 0.08 |
| 13.8 | 135 | 64 | 0.50 |
| 13.8 | 173 | 10 | 0.06 |
| 13.8 | 175 | 24 | 0.14 |
| *13.8 | 124 | 207 | 1.70 |
| 13.8 | 168 | 20 | 0.12 |
| 13.8 | 108 | 49 | 0.50 |
| 13.8 | 265 | 7 | 0.03 |
| 3.0 | 179 | 1 | 0.006 |

*Graphic meter records have shown that frequent power reversals of long duration occurred at this location. Current magnitudes in excess of the relay settings caused the large number of operations noted. These operations have been practically eliminated by readjusting the current elements so that they do not pick up on the current magnitudes normally encountered at this location.

Twenty-nine faults have been experienced on feeders on which network protectors equipped with sequence relays were installed. The operation of the sequence relays on each fault was correct.

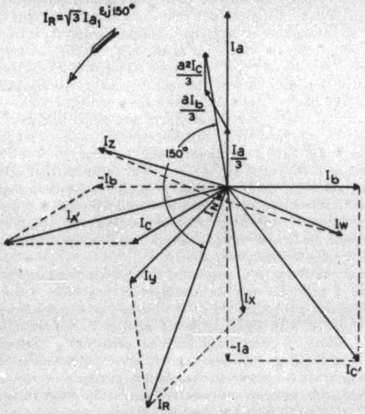

Fig. 10—Unbalanced Current Diagram

Seven 1,600-ampere and four 3,000-ampere network protectors equipped with sequence relays have been installed recently; while eleven 1,600-ampere and five 3,000-ampere protectors with sequence relays will be installed at an early date.

## Tests

Several tests were made to determine the ease with which the ten protectors equipped with sequence relays could be opened after deenergizing the 13.8-kv feeder at the power station. These tests were made on the initial installation when all protectors were connected on one feeder.

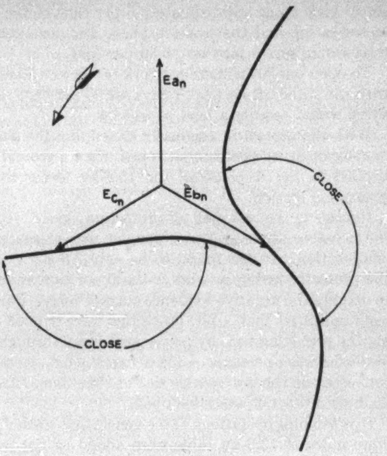

Fig. 11—Operating Characteristics of the Separate Phasing Coil Circuits

Closing torque is developed within a given circuit when the associated feeder voltage terminates within its closing area. The resultant torque is always in the "opening" direction when feeder cables have been incorrectly connected as indicated above:

DELTA-STAR SYSTEMS

| Feeder cables interchanged | Feeder voltage | | Direction of torque | |
|---|---|---|---|---|
| | $E_b$ 180° from | $E_c$ 180° from | Phase *B* | Phase *C* |
| *a* and *b* | $Ea_n$ | $Ec_n$ | Strong open | Strong open. |
| *b* and *c* | $Ec_n$ | $Eb_n$ | Light closing | Strong open. |
| *a* and *c* | $Eb_n$ | $Ea_n$ | Strong open | Fair closing |

With all cables rotated 120° or 240°, both phases will produce opening torque.

If feeder voltage $Ea = 0$, the protector cannot close as the control circuit is connected across phase *A-C*.

STAR-STAR SYSTEMS

When any two feeder cables, other than phase *a* and ground, are interchanged and when all cables are rotated 120° in either direction opening torques will be developed in the relay. When phase *a* and ground cables are interchanged, the low control voltage obtained prevents closing of the protector

Two methods of creating a negative phase sequence current were used:

1. A single-phase load on the secondary side of one distribution transformer bank.
2. Grounding one conductor of the 13.8-kv feeder at the station which causes an unbalance in the charging current.

Using a load connected from *C* phase to ground on the secondary side of 150-kva distribution transformer bank, it was found that a load of approximately 500 amperes at 85 deg or 5.2 kw was required to open the ten protectors on the feeder. Inspection made after the station breaker was opened but before the secondary load was applied showed that no protectors opened previous to applying the load. At the time of the above test, the negative phase sequence current relays were set to pick up at approximately 5 per cent of the protector rating and the positive phase sequence current relays were set to pick up at 30 per cent.

To open ten 500 ampere network protectors equipped with the standard network relays set 30 per cent insensitive would require a load of 540 kw.

With the protectors originally closed and the station breaker open, all protectors tripped when a ground was applied to the *A* phase of the 13.8-kv feeder at the generating station.

Repeating the test with all protectors blocked closed, the negative phase sequence current was measured at one location. It was found to be only 2.9 per cent of the protector rating instead of the 5 per cent required to operate the negative sequence current relay. Further tests indicated that a few protectors were tripped during the preceding test, by power exchanges through the feeder between portions of the network which were not connected on the low voltage side at that time. The remaining protectors cascaded open.

By switching operations at the generating station, five more miles of 13.8-kv cable were added to the feeder without increasing the connected transformer capacity.

After blocking the protectors closed and grounding the *A* phase of this longer feeder, the negative phase sequence current was again measured at the above mentioned location and was found to be 8 per cent of the protector rating, which was ample to operate all negative phase sequence current relays.

Back feed tests on the long 13.8-kv feeder showed that all protectors other than those feeding back remained open and the relays had strong opening torques. Transformer voltages on some protectors as high as 133 volts were obtained during this test.

Complete laboratory tests and operating experience have shown that needless protector operations are practically eliminated by use of this relay. Decreased likelihood of light flicker and reduced wear on the protector result from keeping protectors closed a greater proportion of time than heretofore. Load-back methods of clearing feeders, equipped with insensitive relays, and the resulting disturbances in the network are also avoided. These advantages have been obtained in a single relay, without sacrificing the accurate phasing and tripping characteristics now considered essential to the successful operation of the network protectors.

The authors wish to express their thanks to Messrs. H. R. Searing, R. E. Powers, B. E. Lenehan and C. T. Altfather, whose work has added materially to this paper.

## Discussion

### APPLICATION OF PHASE SEQUENCE PRINCIPLES

(Searing and Powers)

### A SEQUENCE RELAY FOR NETWORK PROTECTORS

(Orcutt and Bostwick)

**W. J. McLachlan:** The desirability of a relaying scheme for network protectors which will result in the elimination of unnecessary operations, with minimum sacrifice in system operating flexibility, has been evident from operating experience in certain systems. These papers present a very interesting approach to this problem.

To the uninitiated the statement that the average number of operations is at the rate of 3 to 5 thousand annually per protector, may be unduly alarming. It should be particularly noted that this statement is qualified as existing "in certain locations." These locations have been generally limited to large metropolitan systems where multiple supply is from several sources, network load is relatively light, and elevator regeneration is frequently encountered. The average annual operating rate in locations other than these is but a fraction of these values. An understanding of this fact is important in evaluating the advantage of a relaying scheme which reduces the operating rate, as opposed to any possible disadvantages in specific applications.

Among the methods cited for obtaining negative sequence current to cause the protectors to be opened is that of earthing one conductor of a delta-connected feeder which has been disconnected from the source. This method will not be found to be applicable in systems on a general scale. Systems with long 22-kv and 27-kv feeders have found it necessary to employ shunt reactors to neutralize cable capacitance, thus limiting the voltage rise on the network and feeder when the feeder is energized only from the network. A recent development in these devices incorporates grounding transformer action of benefit in limiting the flow of charging current under the earthed conductor condition. The action of this device is such that with certain values of cable capacitance no negative sequence current flows from the network when one conductor is earthed. From the tests reported, 7.8 miles of 13-kv cable were required to give 8 per cent negative sequence current through 10—500-ampere protectors on 150-kv banks. Had this feeder been arranged with its full capacity in connecting transformers and all of the associated protectors equipped with sequence relays, the cable length required would have been approximately 4 times as long; 13-kv feeders of such length are rare. It will be found that a feeder having sufficient cable capacitance to give 8 per cent negative sequence current under the earthed conductor condition through all connected transformers, of ratings now in use, will give rise to objectionable overvoltage conditions when the cable is energized through one transformer only.

From the above, it is concluded that the earthing of one conductor is practical only as a temporary expedient where few transformers are connected to the feeder—or where a few only are equipped with phase sequence relayed protectors. In the consideration of general applications, some other controllable source of negative sequence current must be included. Inasmuch as it will be desired to clear feeders in which one conductor has faulted to ground, such controllable source must have sufficient capacity to give the desired minimum negative sequence current, when that existing due to a ground on any phase of the cable is added vectorially to the output of the source. This may require a considerable increase in the capacity of the source over that required to give operation with the cable ungrounded, inasmuch as the negative sequence current due to the unbalanced cable capacitance may be opposite in phase to that of the source.

A second method of obtaining negative sequence current, illustrated in Fig. 5 of the paper by Mr. Searing and Mr. Powers, is described as a small motor-generator set. It is true that the generator of this set may be small—but not the motor. This motor must carry the total negative-phase current and withstand full voltage. Assuming a 10,000-kva 27-kv feeder, with 8 per cent negative sequence current required, this amounts to 800 kva.

Load-back methods of tripping insensitive network relays do not necessarily impose an objectionable voltage disturbance on the network. This may be accomplished without appreciable disturbance by imposing means for circulating current through the feeder to be cleared and the remainder of the system. Generally, such a method will result in less disturbance when one protector only has not opened than any of the methods of imposing negative sequence current which have been mentioned in these papers.

Objectionable unnecessary operations of protectors can be eliminated by the use of non-sensitive relays. Feeders can be cleared without objectionable disturbance when such relays are used. The comparative merit of the sequence relay in cases where the reduction of protector operation is desirable, must therefore be judged on the basis of overall system economy, including load-back means for either scheme, reliability of the relay equipment, and maintenance requirements.

From the practical viewpoint, an objection to this scheme of relaying may arise from the fact that a multiplicity of electrical devices is involved, the failure of any one of which will render the relay completely inoperative either in tripping or closing operation or both. This is contrasted to the more usual relaying methods in which the actuating elements operate in accordance with single-phase phenomena, such that the failure of a single part affects only the operation of the corresponding phase element.

In the arrangement as described, the directional element must operate on the same exacting requirements of current magnitudes and phase angles as the present sensitive relays. Such requirements have been a decidedly limiting factor in the design of network relays. Because of the range of current on which operation is desired, the relay must operate on small torques, with corresponding limitations in sturdiness and overall reliability of the devices. A relaying system which does not impose these stringent requirements would be of obvious advantage. In the sequence relay, the tripping phase angle characteristic is dependent not only on the characteristics of the directional relay elements but also on the exact characteristics of all devices in and associated with the filter circuits. Extreme care must be exercised in the design and manufacture of this equipment to control exactly the characteristics of all devices, or variation in the tripping characteristic will result in failure to meet the requirements.

**J. A. Brooks:** In general the history of development has been that some anticipated conditions do not materialzie and other conditions not anticipated become a problem. In addition some parts of the new device are usually obtained by use of standard equipment developed before for other applications and not particularly suitable for the new functions desired. I believe that our existing low-voltage a-c network protector has not escaped these more or less traditional fates and that we should now carry out the third historical phase of development by materially simplifying the device originally developed. These papers are unquestionably a forward step in this direction.

In the past, manufacturers have been somewhat handicapped by the many requirements specified by the operating companies for network protector operation. In brief these requirements have been that the network protector shall not close unless the feeder voltage is at least equal in magnitude to network voltage, unless the feeder voltage is in phase with or slightly leading the network voltage, and unless the phase rotation of the incoming feeder is the same as that of the network. The opening requirements have specified that the network protector shall not open unless polyphase power is flowing from the network to the feeder and that it shall be possible to adjust the tripping device for operation on magnitudes of backfeed varying from the excitation energy of the associated network transformer to the short-circuit currents and power factors obtainable for all possible network constants. As pointed out by Messrs. Searing and Powers the requirement of sensitive reverse power trip has materially complicated present network relaying equipment, this complication being necessary to prevent pumping operations and to make the sensitive feature operable on the leading backfeeds sometimes drawn by high voltage network feeder cables. The introduction of the phase sequence relay provides a new means for handling these difficulties.

The network relays and network switches used in the present network protectors are fundamentally of the same design as switchboard devices used for several years before the advent of the low voltage a-c network. Switchboard application is different from network application in that a switchboard device can be inspected and maintained easily whereas a distribution device housed in a water-tight compartment located in a street manhole is not readily accessible for inspection and maintenance, also that the number of such distribution devices on a large system will become so great as to make frequent inspection and maintenance a large item. Before the advent of the network protector, distribution devices consisted chiefly of distribution transformers and cable, both of which require relatively little maintenance. The network protector to be entirely satisfactory should be made to approach this ideal as far as possible.

These two papers pertain only to the relay equipment and not to the network switch which also is a source of inspection and maintenance expense. I believe the fact that fuses are now almost universally used as back-up protection indicates that the industry is not satisfied that the present network protector is sufficiently sturdy and reliable to be counted upon for positive operation. There are several undesirable features introduced by the use of the back-up fuse, the chief of which are a material increase in the loss dissipated in submersible network equipment and the use of a straight overload device in series with an elaborate directional device. The elimination of the fuse should make it possible to use smaller subway type network protectors for a given rating and should eliminate troubles which arise in certain service layouts due to the lack of fuse selectivity.

It would seem that the only urgent requirements of operation for network protectors are that they close when and only when the conditions on the associated feeder are normal or when the voltage on all three phases of the feeder exceed a pre-determined value, that the network protector should trip when and only when there is a short circuit on the associated network feeder or a means is applied at the station for opening all network protectors on a feeder. Additional operating requirements may be desirable but a careful analysis of their justification should be made if their use adds complication.

Transmission systems have for a long time been networks of varying extent. They have in most cases been operated by closing all the switches and leaving them closed except when equipment was taken out of service for inspection and repair or when a fault on a part of the system was isolated by relay operation. This method of operating is predicated on the premise that the system must be designed and operated in such a manner that abnormal feeder conditions, except in cases of emergency, will not occur, and usually when such emergency conditions arise it is not intended that more switches in the transmission system open than is required to isolate the trouble. Is there any reason why the operation of the distribution network should be different from the above except that a means be added for voluntary opening of the network switches from the station?

In my opinion the manufacturers of network protectors should develop an entirely new equipment, the relay and switch both designed to go together as a unit, both being as simple, sturdy and reliable as it is possible to make them, this reliability being great enough to allow abandonment of the fuse and the simplicity being sufficient to allow an appreciable reduction in price. The operators should cooperate to the utmost in this development and eliminate all past operating requirements which cause inherent complication in the network protector and which are not absolutely necessary for satisfactory system operation. This development should not be influenced by past prejudices on the part of either the manufacturer or operator, and all component parts of the equipment should be designed and built for distribution application which requires a very minimum of inspection and maintenance and a very maximum of reliability.

**W. R. Bullard:** The method of relaying described in these papers solves, in a very ingenious manner, certain operating problems that have arisen in connection with low voltage a-c networks. This method of relaying, undoubtedly, has its fields of application, probably the major field being that of large networks in metropolitan areas. I believe, however, that the general situation should be very carefully studied before any move is made to make a general change in design of network protectors by incorporating this principle. One thing which should be considered is the fact that many small operating companies are meeting the problems mentioned in these papers satisfactorily with existing equipment. These companies have organizations trained in the use of present equipment and any general change of design would mean considerable inconvenience, both in the problem of stocking apparatus and in the matter of training the personnel to handle the new design.

A number of years ago I wrote a paper outlining my standpoint as of that time concerning operating requirements of network relays. The requirements outlined were rather exacting and complicated. Since that time much has been learned about the operation of networks and some of the anticipated applications of the network principle have not materialized. One of these is automatic synchronization at the load. The present business situation has been a vital factor in revising many engineering standpoints and we have learned, among other things, that many operating conveniences, formerly considered justified, can be properly and economically dispensed with. Another factor in this specific problem is the growing interest that is being shown in the application of low voltage networks to overhead distribution systems which focuses attention on the desirability of low cost and extreme simplicity. In view of all these factors, I now feel that the past tendency in the development of network equipment has been to attempt to make it perform too many functions, and that this tendency has resulted in too many mechanical and electrical complications. Therefore, if any general change is to be made in network apparatus design, I feel that it should be directed toward general and complete simplification. The method of relaying described in these papers is a step toward simplification, but stops considerably short of the goal I have in mind.

One of the present factors which tends to prevent the accomplishment of really worth while simplification is the requirement for high sensitivity, both in the opening and the reclosing functions. If this requirement were dispensed with or materially modified, it seems quite probable that a large percentage of the complications involved either in present equipment or in the method of relaying described in these papers would be eliminated, the result being an extremely simple and sturdy piece of equipment, possibly lacking sensitive relays of any kind, but utilizing instead the direct application of control impulses to the switch mechanism itself. Perhaps, we are not yet prepared for a sweeping change of this kind, but I have a feeling that it will eventually be brought into the general picture. In the meantime, it would seem desirable to avoid any wide spread intermediate change of design in the face of the need for a more sweeping change.

**H. C. Forbes:** Messrs. Searing and Powers point out in their paper several cases where the electrical relationships on the system under what they very properly describe as normal operating conditions may be such as to produce an excessive number of network switch operations. The phase sequence relay which they have developed promises to eliminate the excessive number of operations under these troublesome conditions and since at the same time it introduces other desirable features it will no doubt, receive a royal welcome from the central station industry. This admirable solution of a difficult distribution problem, however, should not be taken by those engineers who are concerned with the design and operation of the system from which the network supply is derived as an occasion to shrug their shoulders and assume that nothing further remains to be done.

On the contrary, the differences in phase angle and voltage which occur on the system at different points still will be present and may manifest themselves in the shape of overloaded distribution transformers and loss in efficiency due to unwanted circulating currents. It is my belief that further effort in the direction of eliminating this trouble at its source would be well rewarded. For example, generating station busses are usually divided into sections which are interconnected by means of reactors or in some cases they may be even more completely segregated by interconnecting them only through system ties and feeders external to the station. Now under such conditions there will assuredly be appreciable differences in voltage and phase angle between the several bus sections in the station unless a definite effort is made to avoid them. I venture to say that in most such stations there are adequate voltmeter installations so that the operators have a satisfactory guide in controlling the voltages but in no station to my knowledge is there a permanent installation of equipment which gives the operators a direct indication of the differences in phase position of the several bus sections. The engineers of the central station companies will do well to give careful consideration to the provision of such facilities. In the meantime the station operators can hardly be severely criticized for not maintaining their bus sections in phase in the absence of any means of knowing definitely when they have accomplished the result.

There are many other ways in which careful design and operation of the power system can supplement the benefits to be obtained from the newly developed relay and there seems no reason to doubt that the improved equipment will go hand in hand with improved engineering coordination of the elements of the central station systems, and that further enhancement of the well deserved popularity of the low voltage a-c network system of distribution will result thereby.

**C. M. Gilt:** The papers presented on phase sequence relays well illustrate the change in thought that frequently accompanies a development of any character. I believe the general application of so-called sensitive network relays has been due to a philosophy of design and operation common during the early stages of the development of the low-voltage, a-c network, but which has not been followed out as operating experience was obtained.

Many of the early ideas were built around the assumption that a successful network required the use of relatively high impedance transformers closely spaced so as to obtain relatively low impedance in the secondary connections between transformers. With such a design proper voltage regulation of the network would be obtained by taking primary feeders and network transformers out of service progressively as the load decreased, so as to obtain approximately constant load on the feeders in service and reduced transformer core losses. Such operation required the use of sensitive relays which would readily trip on exciting current of the network transformer or the charging current of the high-tension feeder when backfed from the network.

As a matter of actual development, networks are commonly built with transformers of normal reactance design and spaced far enough apart so that there is usually a fair amount of impendance between units. The primary voltage is regulated according to load so as to obtain approximately constant voltage on the network, and feeders and transformers are not taken out of service at periods of light load for the sake of regulation or saving of losses. Consequently, one of the principal incentives for the use of sensitive relays has disappeared or never actually developed. Furthermore when it does become necessary to connect two or more network transformers with relatively low impedance between them, the sensitive relay becomes a real handicap in that it trips units on small backfeed due to slight differences in feeder voltages at time of light load and so reduces the transformer capacity that bad flicker and frequent network switch operations result when large motors are started or elevators are operating.

By removing the requirements for sensitive operation, it would appear possible to eliminate other requirements and to simplify greatly the network relays, securing a much more sturdy device that will not require the delicate settings and adjustments of the present relays. It is of course essential that the network switch should trip promptly on high tension feeder failure and that means should be provided for readily tripping the breaker on the few occasions that it is necessary to take the high tension feeder out of service for maintenance or rearrangements.

It would appear that the relay characteristics outlined in these papers provide one method of eliminating the sensitive characteristics of the standard relay, while still retaining the essential features of tripping on high tension feeder failure and providing a means of intentionally tripping the breaker when such needs arise.

It is highly desirable that developments with these objects in view be carried along and particularly it is to be hoped that we may obtain still further improvements in simplicity, sturdiness and reliability of network switches and relays.

**H. R. Searing and R. E. Powers:** Simplification in apparatus ordinarily is accomplished through the reduction in actual requirements in the number of functions performed by the apparatus and a reduction of functions performed must be in order before a more simple device can be produced. With increased operating experience in secondary network systems it is apparent that considerable thought is being devoted to the network protector with the general thought of "laying down the bars" on requirements to secure a more simple unit. This thought applies to future devices not designed at the present time; however, we have many thousands of network units in service today and changing conditions make it necessary to render a large number of these units selective, tripping only on power reversals on the order of 20-100 per cent of bank rating. Negative phase sequence auxiliaries can be added to existing equipment to produce results comparable to that secured from the relays described in this paper, the directional function being performed by the existing three-phase watt element. It is the general feeling that any system operated selectively will require some form of load back method to open protectors from the source. The system employing negative phase sequence current in conjunction with a directional watt element in comparison to the existing proposed schemes will require a minimum amount of terminal apparatus to provide the necessary intentional tripping functions.

With reference to the discussion by Mr. W. J. McLachlan we agree that earthing of a single conductor on a delta-connected feeder which has been disconnected from the source is not a universal solution in providing a source of negative phase sequence current for tripping. In the body of our paper we point out that the quantity of negative sequence current is a function of cable length, voltage and number of banks involved and is thus a variable quantity. In referring to Fig. 5 of our paper Mr. McLachlan calculates 800 kva for the motor of the motor-generator set to accompany a 10,000 kva 25 kv feeder. In considering that particular feeder combination equipped with selective equipment of standard design set at 25 per cent power reversal it would require at least 2,500 kw transfer to cause the protectors to open, and if the current circulated were other than at unity power factor the kilovoltamperes would be greater. Thus relatively the motor-generator set can be classified as small although there will be a difference in the rating of motor and generator. Static apparatus can be employed as a means of providing a source of negative phase sequence current for tripping and may prove to be superior to rotating equipment.

Generally speaking, we intend to use negative phase sequence current to provide an initiating impulse to trip protectors and not to open switches that fail to open mechanically or otherwise.

The only manner in which a protector in that condition can be opened is manually or by opening the associated fuses by the circulation of current through the defective protector and measured at the switch takes, for a 500-kva bank approximately 2,000 kva for a protracted period of time.

Mr. McLachlan states that the directional element of the proposed arrangement is subjected to the same requirements as the present relaying system as far as magnitude and angular relationship are concerned. In the main this is true, however, careful study of field performance shows that the relay has been one of the most reliable and satisfactory portions of the network protector and when properly applied functions satisfactorily. Failures to operate have in the majority of cases been at points other than the relay.

We have encountered no difficulty whatsoever in designing relay and associated filter so as to secure the proper relay characteristics with ordinary shop testing and routine.

**H. S. Orcutt:** The relay described in our paper was designed to meet all the requirements originally considered as being necessary for successful operation of the network protector. While it may seem that the relay is complicated, as pointed out in the discussion, it is in fact no more so than the present relaying equipment since the majority of its parts are fixed resistors and reactors which have been built with a large factor of safety to avoid failures.

We are in complete agreement with the need of further simplification of the network equipment. It was with this idea in mind that the sequence relay was developed in its present form with a single disk directional element and with the new design of phasing circuit, otherwise a negative phase sequence overcurrent element could have been added to the standard relay equipment and satisfactory results obtained. The addition of a negative phase sequence overcurrent element to the present relaying equipment affords a means of eliminating the manual operation of the present non-sensitive network protectors when it is desired to deenergize the feeder.

With the growing feeling toward simplification many of the exacting characteristics required of the original network relays are decreasing in importance or are being eliminated entirely. This undoubtedly will result in the simplification of the relaying equipment. From operating experience in New York it is found that from 80 to 90 per cent of the failures on network protectors are directly contributable to the breaker. We believe, therefore, that the logical place to start simplification or improvements is on the breaker.

# Higher Steam Pressures and Temperatures

## A Challenge to Engineers

BY MELVIN D. ENGLE* and IRVING E. MOULTROP†
Member, A.I.E.E. Fellow, A.I.E.E.

THE optimum steam pressure and temperature for steam-electric generating stations has not been determined. Because of the importance of the subject to the electrical industry, it has been considered worth while to present a resumé of what has been accomplished with comments of such a nature as to provoke helpful discussion.

Fig. 1 shows the operating pressures and temperatures that have been used in the steam-electric generating stations of one of the electrical companies in the United States from 1885 to date, and Fig. 2 shows the improvement in fuel economy that has resulted from the use of higher steam pressures and temperatures and other improvements in station design in the stations of the same company. These curves are typical of what has been accomplished by the electrical industry in general by constant and persistent study of the problem. The second curve in Fig. 2 shows what has been accomplished by all utility plants in the United States—good, bad, and indifferent. These curves indicate that the fight for better economy has been very much worth while but are at the same time a challenge to the ingenuity of the engineers of the future. This better and better fuel economy has been accomplished in general by stations that have cost less and less per unit of capacity in spite of their better economy. Will the engineers of the future be able to meet the challenge?

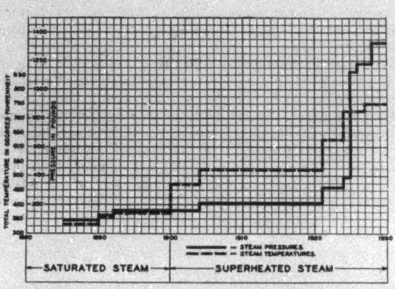

FIG. 1—STEAM PRESSURES AND STEAM TEMPERATURES USED IN THE BOILER PLANTS OF THE EDISON ELECTRIC ILLUMINATING CO. OF BOSTON

Fig. 3 shows a comparison of approximate station heat rates at constant pressure and varying temperature from 750 deg to 1,000 deg F. It shows graphically that no matter what pressure or cycle one may select, the higher the steam temperature, the better the station economy. Most of the problems involved in the use of a steam temperature of 750 deg F have been solved. Some of the new stations now being built will operate at a temperature of from 825 to 850 deg F and within a comparatively few years we will, no doubt, be operating with steam temperatures of 1,000 deg F. The limitations imposed by the materials of construction for superheaters, reheaters, turbines, valves, etc., are slowly being removed and the 1,000 deg F station is no longer a fantastic dream. It will be a reality within the lifetime of many of those living today.

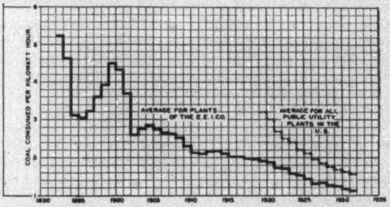

FIG. 2—FUEL CONSUMPTION FOR THE SYSTEM OF THE EDISON ELECTRIC ILLUMINATING CO. OF BOSTON AND ALL UTILITIES IN THE UNITED STATES

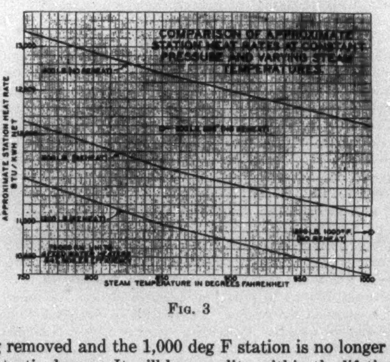

FIG. 3

The problem of the control of the temperature of the steam leaving the superheaters and reheaters is one that must be solved before much further progress can be made, for while we could probably design for nearly 1,000 deg F today, the equipment would not withstand the temperatures that would exist during abnormal operating conditions such as dirty boilers, poor combustion conditions, and changes in the character of the fuel being burned. This problem is being studied and seems well on the way to a satisfactory solution.

---

*Asst. to the Supt., Station Engineering Dept., The Edison Elec. Illuminating Co. of Boston.

†Chief Engineer and Supt. Construction Bureau, The Edison Elec. Illuminating Co. of Boston.

*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

Fig. 4 shows the comparison of approximate station heat rates at constant temperature and varying pressure from 400 lb to 2,500 lb. These curves show that no matter what steam temperature one may select, the higher steam pressures show considerable improvement in station economy when compared with the so-called moderate pressure of 400 lb. The improvement in economy for pressures at least as high as 1,200 lb are of such a magnitude that station designers can not afford to disregard them.

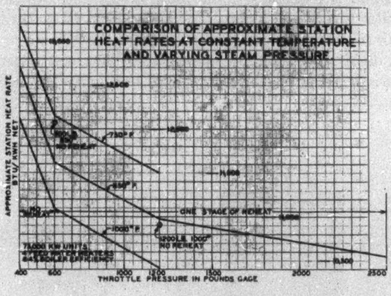

Fig. 4

A number of designers seem to favor a pressure of from 600 to 700 lb and a temperature of from 825 to 850 deg F without reheat on the plea that such a station gives good economy and is simpler than one employing the reheat cycle. It is true that such a station (600-700 lb) will give approximately 5 per cent better economy than a 400-lb 850-deg station but the designer should not overlook the fact that on the same basis a 1,200-lb 850-deg reheat cycle station will give approximately 13½ per cent better economy than the 400-lb 850-deg station.

A number of stations is in service employing the reheat cycle and no very serious operating difficulties have shown up. It boils itself down, therefore, to the question of the unit cost of construction for stations of various pressures and cycles.

It is an extremely difficult matter to determine in advance the exact comparative cost of a new station or an extension to an old station, where the only difference is to be in the steam pressure or steam temperature. The difference in unit cost is a very small percentage of the whole, and an error in design can change the unit cost more than the difference due to pressure or temperature. Those who have actually built stations for moderate and high pressures are not really sure as to the exact difference in unit cost because of the other variables entering into the various designs. However, all of those who have built high pressure stations feel that the higher pressure was justified.

Past experience has shown in general that higher steam pressure does not of itself increase the cost of construction, but actually results in lower unit costs of construction. For example, probably all agree that a 400-lb 750-deg non-reheat station would cost less per kilowatt of capacity than a 200-lb 750-deg station built to operate on the same cycle. It is known, however, that a 600-lb, 750-750-deg reheat station would cost more per kilowatt of capacity than a 600-lb 750-deg non-reheat station.

The probable facts of the case are that the unit cost of construction decreases with increase in pressure as long as the same heat cycle is employed and as long as the pressure does not require a radical change in the design of the pressure apparatus. When a pressure is reached that requires a change in the heat cycle or a radical change in design of the pressure apparatus, the unit cost probably takes a sudden jump and falls off again as the pressure is increased until another change in heat cycle or design is necessary. This idea is illustrated graphically by Fig. 5.

The unit cost of the pressure parts is greater for higher pressure apparatus and so high-pressure mistakes are more expensive than low-pressure mistakes. Our discussion is based on proper design for all conditions.

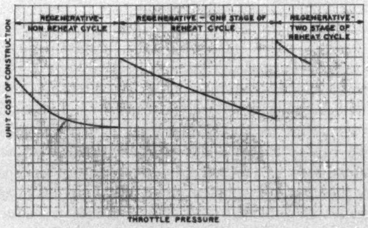

Fig. 5—Probable Variation in Unit Cost of Construction of Steam-Electric Generating Stations at Constant Temperature and Varying Pressure

Fig. 6 shows the additional capital investment per unit of capacity that is justified for a 1,200-lb 750 deg-750 deg reheat station over a 400-lb 750-deg non-reheat station for 40 per cent load factor and various costs of fuel. Where there is a question in one's mind as to the exact unit cost of the high-pressure station it is comforting to know that a considerable increase in unit cost is justified by the higher thermal efficiency.

We are all interested in generating electrical energy for the lowest cost per net kilowatthour. We are also interested in keeping down to a minimum the cost per net kilowatt of capacity of our generating stations. We would be untrue to our trust, however, if we did not design according to our best engineering judgment so as to obtain the lowest cost per net kilowatthour generated. We should endeavor to obtain the highest possible "dollar efficiency."

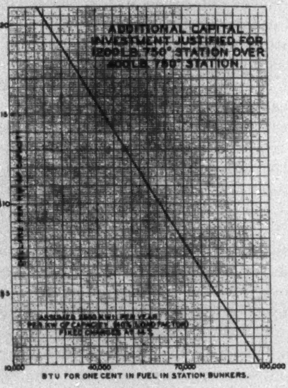

Fig. 6

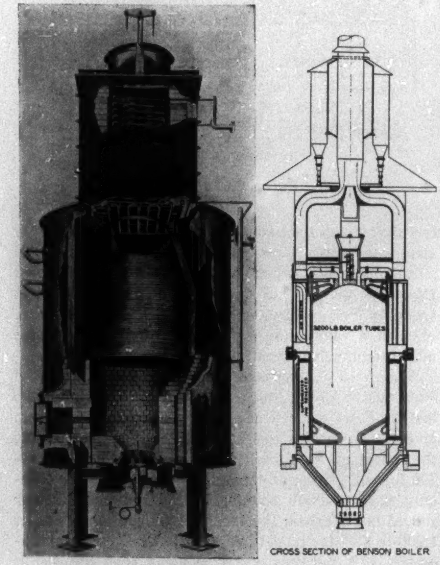
Another important consideration in the selection of the most economical pressure and temperature is the fact that the design and manufacture of high-pressure generating equipment is in its infancy. As time goes on, designs will be improved and manufacturing methods will be changed so that we will be able to install the more economical equipment for considerably less per unit of capacity than we can today. It is necessary, however, that we go through a period of development. If we can promote this development without actual financial loss, by the use of equipment that is economically justified at its present price, we aid in the progress of the art and will reap even greater profits in the future. If we refuse to install the equipment which our engineering studies indicate is the most economical, we are seriously hindering the progress of our industry.

Station designs in which one steam generating unit supplies all of the steam required by one turbo generator unit are becoming more and more generally accepted as the most economical. A properly designed steam generating unit has about the same availability today as the turbo generator unit and this change in design is both logical and justifiable. Furthermore, since the availability of the steam generating unit and turbo generator unit are about the same, there does not seem to be any justification in a station for spare steam generating units. We can expect the stations built in the future to have firm boiler capacity very closely matching the steam requirements of the turbo generator units at full load.

Welded boiler drums are a new development that will probably become more generally used in the future and should result in lowering the unit cost of the steam generating units.

Boiler manufacturers have only recently made any serious attempts to determine the maximum safe capacity of the boilers which they manufacture. This information is necessary if the most economical design of boiler is to be obtained. The boiler units of the future will probably be designed to operate the boiler proper at nearly its maximum safe capacity and heat traps of various kinds will be so arranged as to give the boiler room efficiency that is justified under the particular conditions of the installation.



A B

Fig. 7—Cross Section of Experimental Series Boiler at Purdue University and Benson Boiler Installed in Europe

Where it is possible to use it, we should not forget that the most economical boiler design is one using the longest drums that it is possible to obtain and the longest tubes that will fit in with the particular design. Such a design not only results in the lowest cost of the boiler itself but also gives the lowest unit cost of building and furnace and practically all items that enter into the cost of the boiler plant.

The series boiler has been in use for several years in Europe and the manufacturer claims that such a design results in the lowest unit cost. We have recently had considerable interest shown in this type of boiler in the United States, and two experimental units have been built and tested. The possibilities of this type of steam generating unit warrants further study, and probably commercial trial in the United States. In spite of our natural prejudice against the idea in general, and the many reasons we can think of why such apparatus would be unsatisfactory, the facts of the case are, that they are in service in Europe and operating with some degree of success. The series boiler and superheater may be the answer to our need for superheat control for higher temperatures and may have possibilities that we do not realize at this time.

The use of larger and larger turbo generator units in the past has, in general, resulted in a very satisfactory reduction in the unit cost of the units, their auxiliaries, and the building to house them. Probably larger units will be used in the future than are dreamed of today.

Manufacturers of turbo generators have patterns for turbine shells of various sizes. When they receive a request for a bid on a turbo generator unit of a specified capacity, they usually select the turbine shell for which they have a pattern that most nearly meets the specification and nozzle it for the specified capacity. This is, of course, more economical than to design a new shell for each bid.

Quite often the turbine shell selected is capable of being nozzled for considerably greater capacity, without

any material increase in cost. We should be careful to obtain the maximum capacity from the turbine shells which we purchase, for in that manner we can obtain the greatest capacity per dollar invested in the turbine room.

The development of the higher pressure apparatus has been both interesting and rapid. In fact, the 1,200 lb equipment has been developed more rapidly than the equipment for any of the lower pressures. The designs used have clearly shown what can be accomplished by intensive study by competent engineers and by close cooperation between manufacturers and users.

Figs. 8, 9, and 10 show the various designs that have been used in the development of the 1,200-1,400-lb cross drum boiler from the 143,000-lb per hour boiler installed in the Edgar Station which had a capacity of approximately 3,575 lb per hour per section to the latest design being offered which has a capacity of approximately 25,000 lb per hour per section.

It is not necessary to discuss in detail the changes in design that have been made. A study of the illustrations shows very clearly the development of the apparatus.

Fig. 11 shows the parallel development of the 1,300-1,400-lb multiple-drum bent-tube boiler from the first one installed in the Lakeside station in Milwaukee to the latest ones installed in the River Rouge Plant of the Ford Motor Company in Detroit. They also show that progress is being made although the changes in design have not been as radical as in the development of the cross drum type.

The developments that have been made in the design of the 1,200-lb turbines and boiler feed pumps have been correspondingly satisfactory although the illustrations do not show up the changes as clearly as they do for the boilers.

The first 1,200-lb turbine installed had a capacity of 3,150 kw and was a single valve, twenty-stage unit as shown by Fig. 12. A number of similar machines were built with capacities as great as 10,000 kw but they all

had the disadvantage that their economy at partial load was considerably less than at full load because of the single valve construction. To rectify this shortcoming, multiple valve turbines were designed giving very good economy from one-half to full load. A number of such turbines have been installed and are performing satisfactorily. Fig. 12 shows 1 five-valve design.

Another very interesting development has been the so-called vertical compound design shown by Fig. 13, in which the high-pressure turbine and its generator are mounted above the low-pressure element, resulting in a considerable saving in turbine room floor space and foundations. The largest 1,200-lb turbine generator in service today has a capacity of 110,000 kw but others of larger capacity are under construction.

The development of the high-pressure boiler feed pump has also been very rapid from the first 300 gpm unit to later ones having a capacity of over 2,000 gpm. The difficulties in developing satisfactory high-pressure boiler feed pumps have been accentuated by the lack of suitable variable speed 3,600 rpm a-c motors and by the fact that the water is heated by the extraction heaters to a temperature of about 440 deg F. These two factors and the difficulty of obtaining sound steel castings have been responsible for most of the difficulties that have shown up.

In making the decision on the steam pressure to be used in future construction we should also keep in mind that considerably greater capacity can be installed on a given piece of property if the station is designed for the higher pressures. If the circulating water available is limited, or the cost of constructing the intake and discharge is high because of local conditions, the high-pressure station has the advantage that greater capacity can be obtained from the water available and the unit cost of the intake and discharge tunnels will be considerably less.

Where existing stations are to be remodeled or extended, high-pressure equipment will permit greater capacity to be installed in the existing buildings and can be given load preference and will increase the economy of the whole station much more than the difference in economy between the high-pressure equipment and the existing equipment.

From a consideration of these facts, we can safely say the engineers of the future will meet the challenge of past accomplishments and will build steam-electric generating stations that will show considerably better fuel economy than our present stations and, furthermore, will cost considerably less per unit of capacity.

ACKNOWLEDGMENT

We wish to acknowledge with thanks, the assistance of many engineers and companies who have supplied information and photographs for the preparation of this paper.

## Discussion

**A. C. Weigel:** With the coming of higher pressures required for steam generating units, the question of the fabrication of higher-pressure boiler drums, and other high-pressure vessels connected with the boilers, has necessitated a thorough study, on the part of the manufacturers and the A.S.M.E. Boiler Code Committee, of proper, safe and economical construction.

Physical limitations and shop facilities for the manufacture of riveted boiler drums have normally been limited to material about 2⅝ in. thick, which means that on the average size boiler drums, riveted construction is limited to approximately 500 lb pressure for bent-tube boilers and 750 lb pressure for boilers of the cross-drum type. When the first boilers were built for pressures higher than these, it was necessary to use forged steel drums. The manufacturing of forged steel drums is a very expensive procedure due to the enormous amount of work in the forging of these drums, numerous heatings of the material during the process of the forging and the final finishing or machining of the drums, together with the wastage resulting from the large amount of material that must be discarded to insure the removal of all surface defects caused by the forging. As a result, the cost of the drums on the majority of the high-pressure boilers is, in many cases, more than 50 per cent of the total cost of the boiler. However, there has been one advantage in the use of forged steel drums, that is, that after careful study the A.S.M.E. Boiler Code Committee has allowed the use of forged steel drums of a higher carbon content and higher tensile strength than that allowed in regular fire box steel, therefore reducing to some extent the weight and thickness of the drums involved.

As fusion welding for tank work and pressure vessels has been in vogue for some time and as there has been quite a good deal of progress made in the studying of the procedure and the results obtained from these welds, the A.S.M.E. Boiler Code Committee several years ago, began a thorough study of the requirements necessary to assure uniformity of product and safety when using fusion welding in the manufacture of high-pressure vessels. After several years of study and discussion, the Code Committee, in June 1931, adopted rules for the manufacture of fusion-welded boiler drums. Besides describing to a great extent the method of procedure for manufacturing boiler drums, a principal requirement of the code that is leading to new uses of electricity in fabrication is that pertaining to the X ray test. This requires that all longitudinal and girth seams on fusion-welded boiler drums are to be X rayed or gamma-rayed to prove the soundness of the welds.

### ELECTRIC ARC USED FOR BOILER FABRICATION

A number of processes or procedures are followed by various manufacturers for fusion welding, but so far coated-rod, metallic-arc welding has been adopted almost universally. Plates are prepared with grooves of special shapes at their junction points with the proper slope along the edges of the groove to prevent undercutting and slag formation in the under-cutting. The weld metal must be deposited at a high temperature and puddled in place, using a coated rod of such type as to burn the oxygen in the vicinity while the metal is being deposited and also to coat the layer of hot metal with a protective coating to prevent absorption of oxygen and nitrogen by the hot material which, unless coated, has a high attraction for these gases. Each successive layer of welding must also have a tendency to anneal or stress relieve the underlying layer and great pains should be exercised in inspecting each layer to be sure that the laying in of that individual layer has not caused shrinkage cracks due to unequal expansion. These shrinkage cracks will not appear providing the structure is properly supported and the deposited material is sufficiently ductile. It is usually necessary to deposit, in the bottom of the groove, at least one layer of cooler material, this to act as a filler in the bottom of the groove. This material, being more porous, is cut out and refilled with higher grade material. Due to the fact that the last layer deposited is never of the same quality as the others, it is required to lay on beads so as to increase the thickness of the weld over that of the parent plate. This reinforcing bead need or need not be removed, although for practical purposes and for the correct reading of X ray films, it is advisable that it be removed, either by machining or grinding, as there are always ridges, small slag pockets and defects in this last reinforcing bead, and these may confuse the operator in reading the X ray films with the condition of the center portion of the weld.

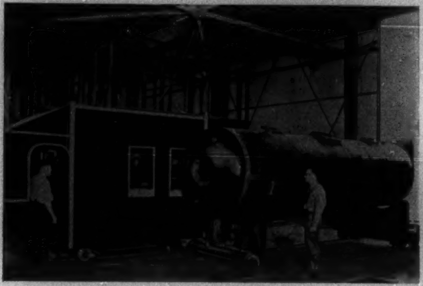

FIG. 1—FUSION WELDED BOILER DRUM BEFORE X RAY APPARATUS FOR TESTING QUALITY OF ELECTRIC WELDS IN $2\frac{1}{2}$ IN. BOILER PLATES

### X RAY USED FOR TESTING OF WELDS

The test plates attached to the ends of the drums for making the physical, chemical, and microscopic tests, if any, indicate the class of welding being laid in but do not give any assurance that the procedure has been uniform and that there is a lack of shrinkage cracks, slag pockets or gas pockets throughout the weld or along the border between the weld and the parent plate.

It has been proved that many processes of fusion welding with proper methods of control, make possible the production of deposited metal, equal or superior, in physical and chemical properties, to the boiler plate. On the other hand, it is undeniable that from its very nature fusion welding leads to greater variance in some respects than the steel plate manufacturing process. Therefore, the question is ever present in the minds of responsible manufacturers and users as to whether a welded seam is as good or better than the physical tested sample coupons. As a result it was necessary to adopt a satisfactory and positive method of non-destructive tests. This was commercially available in two ways: first, by the use of gamma rays, and second, by the use of X ray apparatus. As X ray apparatus was less costly and more readily handled, this has been the universally adopted method for the non-destructive test.

FIG. 2—X RAY PHOTOGRAPH SHOWING SLAG INCLUSIONS AND GAS POCKETS

FIG. 3—X RAY PHOTOGRAPH SHOWING POROSITY IN A BARE WIRE WELD

The A.S.M.E. Code as published at present specifies that for plates of a thickness of 3 in. or less, every portion of all longitudinal and circumferential welded joints of the structures shall be radiographed by sufficiently powerful X ray apparatus under a technique which will determine quantitatively the size of the defect with a thickness greater than 2 per cent of the thickness of the base plate; the X ray films to be submitted to an authorized inspector. Drums or shells of a wall thickness of over 3 in. need not be X rayed until such time as evidence is submitted to the Boiler Code Committee that X ray or similar means are developed that can be commercially applied to greater thickness. The manufacturer shall demonstrate his ability to produce sound welds in boiler drums or shells of a thickness not less than 2½ in., the joints of which are X rayed, in order to be permitted to construct boiler shells or drums with a shell thickness over 3 in. without X ray examination.

The limiting thickness of 3 in. was imposed at the time the code was adopted when commercial installations of X ray equipment were operating at a maximum tube voltage of 200 kv. Since then, however, several X ray installations have been placed in operation with tubes capable of withstanding an applied voltage of 300 kv, which permits X ray examinations of thicknesses of 4 to 4½ in., and without doubt the Boiler Code will shortly increase the requirements so that all plates up to 4½ in. must be subjected to X ray examination.

The Boiler Code also publishes reproductions of radiographs showing porosity and other defects which allow the determination of acceptable and non-acceptable welds. The code limits the serious defects in a welded joint by stating that a radiograph showing a defect, such as slag inclusions or a cavity, whose length exceeds 1/3 $T$ (where $T$ is thickness of joint) and where these defects are not separated from each other by at least 2 $T$, shall be non-acceptable. It further states that in case of such flaws being found they shall be removed and the joint rewelded and re-X rayed. The description of the technique employed must always be submitted with the radiograph to the inspector and this description must give the following information:

1. Thickness of the plate.
2. Distance of the film from the rear of the joint.
3. Distance of the film from the source of X rays.
4. The voltage impressed on the tube.
5. The current flowing through the tube.
6. The time of exposure.
7. The type of film used.
8. The type of intensifying screens.

A further requirement is that reference markers shall be placed along the seams to be X rayed. These markers must be accurately and permanently stamped on the outside surface of the drum or shell near the weld so that a defect appearing on the X ray film can be accurately located in the actual X rayed joints.

The code specifies that a monitor strip 2 per cent of the thickness of the plate to be inspected shall be used for each X ray film. In other words, if sufficient penetration is obtained to reveal the monitor strip which is placed on the boiler plate alongside the weld, the film complies with the code requirements. This monitor strip is used as a gage for determining the intensity of the defects. However, except where the reinforcement has been removed, it is apparent that a greater thickness has to be penetrated to reveal the defects in the weld proper than is necessary to reveal the monitor plate. In other words, on a 2-in. thick boiler plate the monitor strip will be 4/100th of an in. in thickness while the actual weld thickness would be approximately 2¼ in. including the reinforcement. Since the exposure time is a logarithmic function of the plate thickness to be penetrated, we see that with a given voltage and current applied to the X ray tube the weld proper will require an exposure twice as long as that required by the plate to obtain the same film or to detect defects in the same intensity. In other words, when the picture is taken in compliance with the present code, the exposure specified by the outside monitor piece is only about 50 per cent of that necessary to penetrate the weld proper adequately. For this reason it is very probable that a new type of gage will be adopted for determining the depths of defects.

Several studies have been made into the effect on the technique of welding, of the distances from the target to the weld and from the weld to the film. Since the image obtained on X ray films is a projection whose source is the focal spot of the target, the relations give a clear picture of the conditions involved. It is readily seen that since the focal point is not a combined source, sharper definition will be obtained with greater target to weld distance. Also the closer the film is to be to the object, the sharper will be the definition and the less the magnification of the defects shown on the film. However, since exposure time places a practical limit on the target to weld distance, a certain degree of sharpness must be sacrificed. The amount of distortion of defects with the target the same distance from the film increases the distortion of other defects on the target side of thick plates. Therefore, it is becoming necessary to make a table specifying the distance of a target from the plate on different thicknesses of material, and also to specify the distance from the front side of the plate to the film. The distance from the target to the film that seems from experience to be the most acceptable, is to vary 14 in. on plates from 1 in. up to 36 in. for plates 4 in. thick, and to require that a distance from the back of the weld to the film be held constant with a maximum of 1 in. This procedure will limit the maximum distortion of the edge of images from approximately 1.07 on 1 in. material to approximately 1.156 on 4 in. material.

With the above limitations as to the locations of material to be X rayed and the films, no trouble is encountered in the X raying of welded seams with respect to detecting cracks, incomplete fusion, elongated slag pits or other similar defects, such as elongated, closely-connected voids along the wall of a joint. Permissible and non-permissible defects of this type may easily be described quantitatively and the present limit of ⅓ of the thickness for these slag inclusions or cavities is satisfactory. So far it has been impossible to devise quantitatively the degree of porosity (defects in metal structure due to gas bubbles or slag inclusions) as shown on radiographs to limit satisfactorily the acceptable porosity in welds.

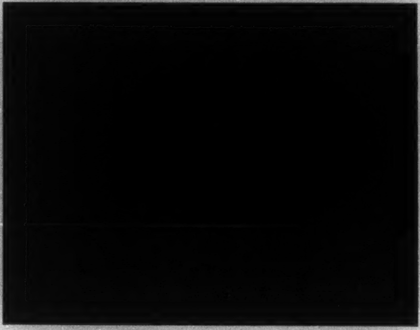

FIG. 4—X RAY PHOTOGRAPH SHOWING EXCELLENT WELD OF 2½ IN. PLATE

However, consideration is being given to this problem and there is no doubt that satisfactory standards will soon be adopted establishing more definite classification of allowable porosity and size and location of flaws, if they exist.

**D. S. Jacobus:** The authors of the paper should be congratulated on the successful outcome of their pioneer work in using high pressure steam for central power plant service. It required courage to install the first unit for 1,200 lb working pressure. There were many ideas in regard to the best form of boiler to use for the purpose. A drumless forced circulation boiler was considered, such as the so-called series boiler on which experiments extending over a number of years had been made by the writer's company. Various forms of natural circulation boilers were also considered. That the choice made was a good one has been shown by the results secured and the great number of high pressure boilers built along similar lines which are now in service.

It is easier to look back on accomplishments than to start at the beginning and overcome difficulties that may arise. There were many features to consider. At the time the first unit was ordered no means had been developed for determining the water level. Mr. Moultrop will remember the comments that this feature caused when it was discussed informally at one of the meetings of the Boiler Code Committee, as it seemed out of line to proceed before such an important question had been solved. Mr. Moultrop was convinced that high pressures would eventually be used and had the spirit of a true pioneer in proceeding with the development with the knowledge that certain features would have to be worked out and that there might be unforeseen difficulties.

A number of devices were suggested and tried for measuring the water level. After a painstaking investigation a water gauge glass was developed which met the conditions. The first boiler operated successfully from the start. There were certain minor troubles which were remedied but nothing of a fundamental character. In the boilers which followed there were further developments such as in the use of water-cooled furnace walls connected to the boiler circulation. The success of these boilers makes it seem that there is no particular reason from an operating standpoint why boilers of other types than those employing a natural circulation need be developed for the pressures and conditions under which they are used in central station practise.

The high head boiler shown in Fig. 10 was designed some time ago with an oil fired furnace for a high steaming capacity per section. In some later developments for pulverized coal firing it was found that a two-pass arrangement with the superheater and reheater in the first upward pass could be used to advantage.

It is stated in the paper that the series boiler may have possibilities that we do not realize at this time. The late Mr. Frederick Sargent was much interested in experiments which the writer's company made on this type of boiler, which began in 1916, and was convinced that there were possibilities of using a boiler of this type for power plant service, notwithstanding the care and skill required to operate it and certain untried and unsolved features. We coined the word "series boiler" to cover the arrangements that we tested, the first of which was a once-through forced circulation boiler with no steam and water drum, the second a forced circulation boiler with a reservoir into which the steam and water from the boiler passed before conducting the steam to the superheater section, and the third a forced circulation boiler used in connection with a natural circulation unit. Water was re-circulated through the boiler in most of the tests made on the second arrangement with the reservoir and in others the conditions were made such that no water accumulated in the reservoir in which case it served simply as a mixing chamber. The forced circulation boiler used in connection with the natural circulation unit was the forerunner of the so-called Calumet boiler and economizer arrangement, which has been largely used, and represented the type of installation that our experiments had shown to be the easiest to operate. Of the three arrangements first tested the once-through boiler with no steam and water drum was the hardest to operate. Tests of different forms of series boilers followed which finally led to the boiler installed at Purdue University, shown in Fig. 7 of the paper, and the automatic control supplied with this boiler which overcomes the operating difficulties experienced in the once-through series boilers first tested. With a boiler of this type all of the impurities in the feedwater pass from the boiler along with the steam, whereas in the Calumet arrangement and where the steam and water are conducted to a reservoir and some of the water is recirculated, clean steam may be secured with impure feedwater. This feature is referred to as it has assumed great importance in connection with central power plant service where we are called on to supply clean steam, and where in many cases washing the steam by water of a greater purity than contained in the boiler is resorted to. Features of this sort must be considered before installing a series boiler for central power plant service, in the same way that features that might give trouble had to be considered by Mr. Moultrop before installing his first high pressure boiler.

If the steam pressure approaches so closely to the critical that a natural circulation boiler cannot be used, a boiler of the series type would have to be employed. There are also certain special conditions involving the use of boilers of a minimum weight and height where a series boiler could be used to advantage.

Mention is made in the paper of regulating the temperature of superheated steam. This becomes more and more important as the temperature of the steam is increased. There are a number of ways in which this can be and has been done. At the South Amboy Station, of which a side view is shown at *A* in Fig. 9, the temperature of both the primary steam and the reheated steam is regulated and there is no reason why this should not be done in any case when so desired.

As stated in the paper, welded boiler drums are now developed that will probably become more generally used in the future and should result in lowering the unit cost of the steam generating units. All of the steam and water drums for boilers that have been built by the writer's company for working pressures of about 1,400 lb have been of seamless forged construction, nearly all being made of steel having a minimum tensile strength of 75,000 lb per sq in. in accordance with the specifications given in the A.S.M.E. Boiler Code. The rules for fusion welding in the A.S.M.E. Boiler Code do not cover the welding of steel of as high a tensile strength as this. The art of fusion welding is advancing rapidly and has been developed for safely welding steels of the higher tensile strengths; additional provisions will no doubt be included in the Boiler Code when the proper specifications and rules for safeguarding the constructions are available. A number are working actively on this problem, as well as on other features of fusion welding. It is believed by those best qualified to pass judgment that eventually fusion welding will be developed to a point where the highest quality will be used under the same rules as for solid plate, with no deduction for the strength of the weld, but each step must be based on scientific evidence and fact and the progress in formulating and adopting rules of the sort must necessarily be slow in order to insure safety.

**G. A. Orrok:** The authors of this paper have presented a history of high pressures and temperatures illustrated with examples of the most interesting of the American plants and we may note here the development of both the boiler and the turbine as applied to the high pressure plants in this country. It will be noticed that most of the development has been done with the usual design of straight tube and bent tube boilers, Fig. 10 alone being a departure and this only in a small measure from the standard types of construction.

In Europe, however, the attempts toward high pressures have led designers and constructors to the indirect as well as the series boiler. There are quite a number of the Schmidt indirect boilers in actual operation at pressures from 600 to 1,500 lb also the Loeffler boilers of which 7 or 8 boilers are in service at about 1,800 lb pressure with what is probably the highest commercial temperature of superheat, 932 deg. Besides these boilers we have the Sulzer single tube type which has just been introduced and the new boilers of the Atmos type with the revolving elements which are being experimented with in quite a number of places in Europe. Perhaps the most interesting developments of the European high pressure boilers is the velox boiler of the Brown Boveri Co. of which two units have been built and three more are under construction. The work of Escher Wyss and Company and Brown Boveri in the high pressure turbine field up to 2,800 lb pressure has been illustrated many times and these units are in daily operation. The question of centrifugal feed pumps seems to have been solved, one of the most satisfactory arrangements being that at Langerbrugge where the full steam pressure is used in the feed pump unit.

In general, it would appear that the costs of these high pressure stations do not exceed low pressure stations of about the same rank of economy or at the best, the differences do not exceed 5 to 10 dollars per kilowatt of prime cost.

In September 1930, before the British Association for the Advancement of Science in a paper on this same subject I showed some curves of the attainable use of heat per kilowatt hour sent out which are somewhat similar to those shown in Fig. 3 and on this plot I spotted a few of the annual station records which have come to my knowledge in the last few years as showing how closely our modern stations come to what might be considered as the standard of efficiency. This illustration (Fig. 5 of this discussion) shows the attainable curves as well as the median line drawn through the station record points. The study of some of the points will show that in a number of cases the modern stations with good load factor have exceeded what I term my ideal case, while in much of the earlier work the influence of low load factor is much more marked.

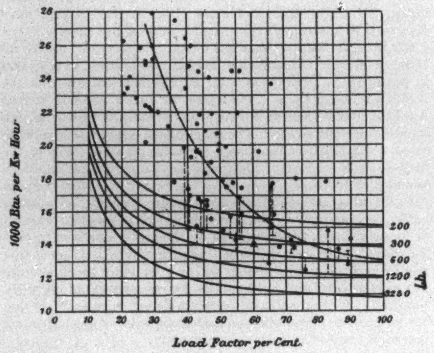

Fig. 5

We probably are still far from the point where we may pick out the ideal pressure and temperature which will give the best results over a wide field and I am personally inclined to believe that for a given load factor the optimum working pressure will probably not exceed 1,800 or 2,000 lb, while it is most probable that at smaller load factors lower pressures, 600 to 900 lb, without the use of reheat might lead to equally good commercial results. Meanwhile, the trend apparently is toward individual units with little cross connection and the best returns are always to be obtained in those stations in which the load factor is large and the loads are comparatively steady.

**F. A. Scheffler:** It does not seem possible that in 1884, when the writer first entered the boiler business, that practically all of the stationary boilers, principally horizontal tubular, portable, and vertical, were constructed in the most haphazard way and insured by reputable boiler insurance companies.

Rivet holes that did not coincide within an eighth of an inch—and sometimes more—were easily corrected by a drift pin, and the rivet driven home. This was *not* good boiler practise but it was permitted universally by the largest boiler manufacturers. One or two such firms did so much business, that, as they gave an insurance policy for one year free with each boiler, it was necessary to keep a resident inspector at the plant all of the time.

How was this inspection carried out and on what kind of a test was the policy given? On nothing more nor less than a hydrostatic cold water test—150 lb for 100 lb boiler pressure. If the boiler was tight at that test pressure, it was suitable and the boiler passed on and shipped to its destination, the certificate being sent by mail when countersigned by the home office of the insurance company. This does not intend to imply that the insurance company did not make strenuous endeavors to improve this horrible practise of riveting. After I had been at the plant about two months the vice president of the insurance company had a private conversation with me and described his past failures so that the manufacturers would realize that certain practises and methods of "laying" out sheets for punching should be changed and improved. He asked my cooperation, which I gladly gave him, but it required considerable time, diplomacy and some expense, to correct these troubles.

The very excellent work of the A.S.M.E. Boiler Code Committee and acceptance of the code by the States generally, has eliminated the careless and indifferent practise heretofore carried on. We now have, as further improvement in boiler construction, welded drums, and accessories, and in addition, satisfactory X and other rays for determining how perfect the weld is.

Credit should be given to the manufacturers for the wonderful research work they have carried on for several years in developing the welding art with all that that implies, to the present state of perfection.

**A. A. Potter:** The following information concerning the series steam generator at Purdue University may prove of interest:

The steam generator illustrated in Fig. 7A was designed and built for Purdue University by the Babcock and Wilcox Company It consists of a cylindrical water-cooled furnace placed immediately beneath a counter-flow economizer or convection section. There is no steam drum and the water which enters this steam generator passes through a continuous coil and leaves it as superheated steam. Outlet pressures of 3,600 lb per sq in. have been carried on this unit. By varying the ratio of fuel to water at a given flow rate the unit will discharge anything from warm water to superheated steam at 830 deg F. The feed water is delivered to the top of the convection section, where it is divided into two parallel circuits of equal length and flows downward countercurrent to the direction of the gas flow. The water as it leaves the two parallel circuits at the bottom of the convection section is carried to the bottom of the furnace coils by a single downcomer or equalizer. A sensitive automatic control system was developed by the Bailey Meter Company for the Purdue University unit, which is based on the thyratron tube as the source of power for the elements which regulate the supply of fuel, air and water.

Oil is used as fuel for this experimental unit, which was designed to deliver about 6,000 lb of steam and to operate at pressures of 1,000 to 3,600 lb per sq in. at the outlet, although at the lower pressures the friction loss is excessive on account of the small tubes used.

Selector switches are provided on the control panel so that the steam generator may be operated on manual control, automatic control, or a combination. The unit has been controlled automatically at outlet pressures varying from 1,500 to 3,527 lb per sq in., at final temperatures up to 830 deg F, and under rapid load changes equal to the entire range of the feed pump motor. The effectiveness of the automatic-control system increases with the pressure since, at the higher pressures, the specific volume of the steam is affected less by changes in temperature than at lower pressures. Normally, about 40 minutes is taken to bring the cold boiler up to operating conditions and to put it on automatic control, although this can be done by one man in about 20 minutes.

In a paper which was presented before the American Society of Mechanical Engineers on December 1, 1931, reports were given concerning the characteristics of the Purdue University series steam generator when operating at a variety of capacities, pressures and final steam temperatures. The behavior of the unit on a swinging load under automatic control was also demonstrated. These preliminary tests indicated that the efficiency of this steam generator varied between 60 and 70 per cent with a water evaporating capacity of 2,000 to 4,280 lb per hour and an outlet pressure range of 2,507 to 3,527 lb per sq in. Higher boiler efficiencies cannot be expected from an experimental unit of this type and size having a short, single pass convection section and a very high stock temperature. In a commercial installation this type of steam generator undoubtedly would be equipped with air heaters.

Since the preliminary results were presented before the A.S.M.E. the following studies have been undertaken:

1. Tests have been carried on with variable amounts of excess air and constant fuel input to determine the effect of furnace conditions on heat transfer rates.

2. Effect of fineness of atomization on the performance and heat transfer notes have been studied.

3. The limitations and practicability of the automatic control system have been investigated.

4. A special type of condensing calorimeter has been developed and was calibrated at temperatures up to 900 deg F and at pressures up to 3,500 lb per sq in. In a paper presented before the A.S.M.E. in December 1932, results of the measurement of entropy by the use of this calorimeter were reported. These included pressures varying from 1,900 to 3,500 lb per sq in. and temperatures of 709 to 780 deg F.

5. The laws governing fluid friction of steam at pressures up to 3,500 lb per sq in. and temperatures up to 830 deg F are now being investigated. Inasmuch as the film coefficient of heat transmission at the inner surface of a boiler tube is a function of the surface friction, the determination of the head loss should also supply fundamental data of use in calculating the temperature gradient from the outside surface of the tube to the fluid within the tube, when subjected to high rates of heat transfer. The determination of the head loss and the fluid film coefficient of heat transmission are of major importance in the design of high pressure forced circulation boilers. Viscosity of steam at a variety of pressures is a part of this study.

The investigations completed and those now in progress indicate that the series steam boiler is practical for a variety of pressures if equipped with a sensitive automatic control system. It is hoped that the studies now under way on fluid friction will result in new information of value to designers of this type of steam generator.

Suggestions will be appreciated concerning studies which should be undertaken at high pressures and of direct value to industry.

**G. G. Post:** To decrease investment costs of power plant equipment and, if possible, to improve present high reliability and efficiency standards seems to be the major challenge to engineers. Efficiency gains from exceeding 1,200 lb pressure are slight, as the authors show, because of rapidly increasing feed-pumping costs and steadily decreasing energy gains. It seems that the industry will gain most by reducing first costs through standardizing on a top pressure and advancing only slowly into higher temperature fields where extremely expensive metals and equipment are necessitated. Since October 1926, 1,200 lb pressure has been used at Lakeside with creditable performance. Availability has been consistently high. During the past year the four high pressure boilers had a combined availability factor of 93.7 per cent and the four high pressure turbines had 96.9 per cent availability. Each boiler-turbine unit averaged 22 starts and stops per month. Maintenance costs have been no higher on the 1,200 lb equipment than on the 300 lb. In 1931, 65c. per boiler per hour of operation was spent on maintenance for the four high pressure boilers. The amount would be reduced to 18.1c. per boiler per hour if the charge for changing the design of radiant superheater elements from the square to the round section in the original boiler were eliminated. Low heat release furnaces with steam and water cooled walls are the major reasons for these low maintenance costs.

The authors speak of the control of steam temperatures leaving superheaters and reheaters as a problem yet to be solved. Combination convection and radiant superheater and reheater surfaces offer a solution which will automatically control steam temperatures and maintain them almost uniform for loads varying from full to quarter. There is no need of separate reheat boilers, unreliable desuperheaters, nor partially effective mechanical dampers with this arrangement. Reheat in the same single boiler-unit in which the steam is originally generated obviates the necessity for proportioning steam to reheaters. Simplicity of operation as well as safety are major merits of the design mentioned. Reheat, as practised at Milwaukee, introduces minimum complications into the cycle. Operating performance at Lakeside offers absolute proof that it is not necessary to go to the series boiler-unit to find the answer for superheat control at higher temperatures.

Investment studies have shown that 1,200-lb equipment at Lakeside actually costs but $5.64 per kilowatt more than 300-lb equipment of equal generating capacity. A comparison of operating statistics with those of a new and modern 300-lb plant running under identical load conditions shows an actual fuel saving of 15.2 per cent for 1,200 lb over 300 lb. With coal at $4.00 per ton, or 64,000 Btu for 1c., it can readily be seen through reference to the authors' Fig. 6 that 1,200-lb equipment has netted a handsome profit.

Six years of operating experience with 1,200-lb equipment confirms the authors' statement that there seems to be no justification for spare steam producing units in a station, and that stations built in the future can be expected to have firm boiler capacity closely matching the full load steam requirements of the turbine-generator units. The Port Washington station is being built on this basis. It will initially have an 80,000-kw turbo generator using 1,230 lb gage steam pressure and 825 deg F steam temperature at the throttle and 825 deg F at the reheat point, and the single boiler will have a capacity equal to the turbine capacity at 90 per cent power factor, or 85,000 kw. Extensions are planned on the same basis.

Exception is taken to the statement concerning the progress made in the development of the multiple-drum bent-tube boiler from the first one installed in the Lakeside station in Milwaukee to the latest ones installed in the River Rouge Plant of the Ford Motor Company in Detroit. That the Ford Company installation represents progress is questioned. The layout at the Ford Plant was dictated by limitations imposed by having to install the equipment in an existing building, and for such limitations only, the design adopted by the Ford Company may be economically justified. When there are no such limitations it has been found that the three-drum bent-tube design fired from one side only, having boiler and not steam reheating, and with heat reclaiming equipment direcly behind the boiler, induced draft fans at or near the ground line, and a stack on the ground, is by far the most attractive from both an investment and an operating standpoint. Faith in this arrangement again is demonstrated at Port Washington where a design very similar to the original Lakeside high pressure design was found best. The *W* design Ford boiler with its heavy attendant supporting steel and a duplication of certain operating personnel, is not an improvement over the single sided design. Steam reheat, rather than boiler reheat, is considered a step backward.

In a 1,200-lb cycle, it is not necessary to pump water at 440 deg as mentioned by the authors, for the high pressure boiler feed pumps can readily be placed in the cycle ahead of the extraction heaters. The pumps can then take water at about 200 deg F and force it through the heaters at the higher pressure. Besides the advantage of handling low temperature water at a fairly constant temperature level, this plan requires approximately

15 per cent less pumping energy because of the higher density of 200 deg water.

**G. L. Knight:** The writer heartily endorses what the authors say about our duty to design for the highest dollar efficiency. However, there is a side to this question of power house design which must not be lost sight of. If additional generating capacity is necessary at a definite time, it may be necessary to be more conservative in our engineering than if, on the other hand, there is available time for experimenting with and working out the problems in installation.

By the same token if pioneer equipment has to be installed considerably ahead of the time it can be made assuredly reliable, then the interest charges during such an interval must be placed as a debit against the new design. Furthermore, where a station has been developed along certain definite lines for a considerable period, and experience has taught designers and operators how to make conservative designs even more reliable, it may be and usually is the part of wisdom to complete the station with similar equipment. This has been the case with the Hudson Avenue Station in Brooklyn, where 320,000 kw of capacity has been added during the past year at the same pressure and temperature as previously installed. The results, we believe, have justified the judgment exercised since the station has operated for the year 1932 at the average heat rate of 13,990 with a best month of 13,320 Btu per kilowatt hour.

Two 160,000-kw, 400-lb units, one placed in commercial operation in January and the other in May, have turned out approximately 1,000,000,000 kwhr of the 1,600,000,000 kwhr generated at Hudson Avenue during the year, or 1.3 per cent of the total utility generation in the country for 1932.

If I were to be concerned with the design of a new station today for the Metropolitan area, I would seriously consider 200,000-kw units at 1,200-lb, and 1,000 deg temperature, and at this temperature the reheat cycle can be eliminated in the interests of simplification without material sacrifice in economy. Such a station would be made as simple as possible with one boiler per turbine and practically no cross connections or duplication of auxiliaries. As part of a system having installed generating capacity of two and one-half million kilowatts, I believe sufficient savings in capital additions could be made by such simplification as would offset extra charges due to occasional necessary outages of such complete units, even though they were the most efficient on the system for a considerable period after their installation.

**R. C. Powell:** Messrs. Engle and Moultrop have given very clearly and concisely the present status of high pressure and temperature steam plant design.

As one who has had experience in the design of both moderate (450 lb) and high (1,350 lb) pressure plants, the writer wishes to confirm the statements given in the paper relative to the costs as affected by pressure. It is true that the costs are influenced to a much greater extent by the general design than by pressure, and the writer believes that on the whole increasing pressure up to 1,350 lb has a favorable effect upon costs. It is difficult to compare precisely the costs of plants since no two plants are sufficiently similar in design. The cost per kilowatt for two 50,000 kw vertical compound units with three boilers operating at 1,250 lb throttle pressure, 750 deg F with 750 deg F reheat was appreciably less than that for either of two 450 lb, 700 deg F plants each consisting of one 37,500-kw unit and two boilers. The cost for the 450-lb plants did not exceed $70 per kw which confirms the statement of the authors that increased efficiency has been obtained along with lower investment cost. The larger size of units for the higher pressure and the installation of two instead of one unit had, of course, a favorable effect upon cost which further confirms the statement that design and other factors may have more influence than pressure.

The actual gain in fuel economy for the higher pressure and somewhat higher temperature is of the order of 15 per cent.

In any consideration of the best pressure and temperature, the fact should not be overlooked that 1,250 lb pressure and 825 deg F with 825 deg F reheat is an established success whereas any moderate pressure, say 450 lb with temperature sufficiently high to even approach the efficiency of the higher pressure is still in the experimental stage. The writer agrees fully with the statement that temperature control is absolutely essential to successful and safe operation with high temperatures.

It appears to the writer that the economics are all in favor of higher pressure. There is no reason to assume that if high temperature, say 1,000 to 1,200 deg F, is successful at 450 or 650 lb it will not be so for 1,250 lb with a considerable gain in efficiency. It is not a difficult or expensive matter to increase the steam temperature with existing boilers, but nothing remains except complete abandonment if higher pressure is to be obtained. Hence, existing 1,250-lb plants may be changed for higher temperatures when they arrive. This will have a very favorable effect upon obsolescence which in the writer's opinion may be one of the serious problems of the future. It is certainly a problem now to many industries which at one time appeared as secure as the power industry at present.

Another advantage of high pressure not brought out by the authors, is the improvement in operating flexibility. The two years experience at Station A in San Francisco has fully demonstrated the operating advantage of 1,250 lb as against 450 lb. A number of load dumping and fast pick-up tests have been made. A load of 65,000 kw which is the maximum continuous rating for each of the units has been dumped a number of times with no case of tripping on overspeed. The load on each unit has been increased from 10,000 kw to 50,000 kw in 34 seconds with no carry-over and with very little disturbance to primary superheat or reheat temperatures. The reheat temperature is automatically controlled. The drum water level is automatically carried about 2 in. lower at light load and this is just about the swell when the load is suddenly applied to the boiler.

Fears regarding reheat complication either in design or operation are not well founded.

In every respect the use of high pressure at Station A, which is operated not on base load but as auxiliary to a large water power and transmission system, has exceeded expectations and the writer agrees with the authors' conclusions that future plants will have better efficiencies at lower costs and in addition better operating characteristics.

**Wm. S. Monroe:** About 10 years ago after our first 600-lb pressure plants had been laid out and we first began to make studies for a practical installation at 1,200-lb pressure, the estimates of cost for equipment indicated such an increase over that for 600 lb as to make the economic value of the higher pressure very doubtful. But the advances of the art have changed this condition, especially the improvements in boiler design for the higher pressure, and the improvements in the technique of boiler construction have so reduced the costs of the higher pressure boilers that our studies for the 150,000-kw State Line Unit No. 2 indicated that the cost of the 1,200-lb installation for a unit of that size would be little, if any, more than for a 600-lb plant.

There are many factors that tend to make the higher pressure plant less expensive. It is really the temperature that is the governing feature today, rather than the pressure. The 1,200-lb design enables reheating to be done at a higher pressure and carried to a higher temperature. The improvement in heat rate is about 8 per cent at 1,200 lb over 600 lb with 825 deg F initial temperature in both cases when full advantage is taken to reheat to 825 deg F at the most efficient pressure, with, of course, extraction for feed heating.

1. So far as the turbine is concerned, the higher pressure unit in a large size will probably be cheaper.

2. In the boiler plant, while the actual cost of the high pressure parts is somewhat higher for 1,200 lb, owing to the decreased

heat rate per kwhr, the cost of the complete boiler unit, including auxiliary equipment, is not greatly affected.

3. As the specific volume of the steam at 1,200 lb is about half that at 600 lb at the same total temperature, the high pressure pipe sizes are reduced in the ratio of about 1 to 1.4 in diameter, and often one pipe can be used in place of two that would be required for large units at 600 lb. The result is that the cost of piping for a large 1,200-lb unit is not increased at all and may be even less.

4. The auxiliary power, generally speaking, is decreased in the ratio of the decreased heat rate with the exception of the boiler feed pump, but when a reciprocating pump is used, the increased efficiency over that of the centrifugal pump more than covers the extra fixed charges due to the cost.

Though the throttle pressure is practically doubled, the safety valve pressure is increased in the ratio of about 1.75 to 1, and the boiler feed pump pressure to about 1.6 to 1. However, the pump efficiency is increased in the ratio of about 1.3 to 1 and the amount of water pumped decreased by about 1 to 1.2, consequently the boiler feed pump power is increased by $\frac{1.6}{1.3 \times 1.2} = 1.025$, or about 3 per cent, therefore practically no increase in total auxiliary power is expected. As against this, of course, the reciprocating feed pump is more expensive than the centrifugal, but not prohibitively so.

**W. I. Slichter:** At a recent meeting of the newly formed Institute of Public Engineering a session was devoted to costs of distribution. The representatives of the public service commission brought out data to prove that the cost of distribution could be brought down to 3 to 4 cents per kwhr. The representatives of the operating companies gave data to show that the cost could legitimately be as high as 9 to 10 cents per kwhr. This gives a mean of about 7 cents per kwhr. Now it is well recognized that the costs of generation at the power house range from 0.3 cent to 1 cent with a mean of about 0.7 cent. This raises the question whether, if a given amount of capital is available for improvement, it should not be spent on the distribution system where each gain of 1 per cent in efficiency will save 10 times as much in the actual cost of energy delivered as would 1 per cent gain in efficiency in the power house. In other words, would not the companies be wise to allocate 10 times as much capital to the distribution system as to the generating system?

**Glenn B. Warren:** The challenge which Mr. Moultrop gives to engineers is indeed one which should be carefully considered and be taken up, but it seems to me that in this connection there still is a greater challenge which the success of this high pressure development and the success of the mercury vapor process have issued, not only to engineers, but to the electrical utilities and to industry in general. This challenge is the opportunity which the successful development of the high pressure process and the mercury vapor process presents of combining plants capable of supplying jointly the electrical demands of the utilities, and the heat and electrical demands of industries, with resultant greatly reduced fuel consumption.

Of course, it will never be possible to secure such coordination of power and heat demand as to obtain complete utilization of all the opportunities presented for such savings. The relation in magnitude and time between the heat and power loads of the industries and the power loads of the utilities will never permit of perfect coordination. Each individual case must be considered on its merits, and the new equipment required can generally be justified economically only when there is a demand for the extra capacity which it produces.

On the other hand, an associate of mine recently made an estimate which showed that if all the industrial back pressure and bleeder turbines manufactured in each of the years 1927 to 1929 inclusive had been built for 1,200 lb initial pressure instead of the 200 to 400 lb pressure which they were built for and arranged to supply the same heat, these turbines would have had an aggregate capacity over and above what they did have equivalent to about one-fifth of all the condensing turbines manufactured in the respective years. Such installations would have been able to produce power on a net additional fuel consumption chargeable to power of about 4,000 Btu per kilowatt hour. Similarly, an extension of this investigation indicated that if all of these turbines which were installed to supply heating steam had been of the mercury vapor process type and as before arranged to supply the same demand for heat, these installations would have had an aggregate capacity over and above what they did have equivalent to almost one-half of that of all the condensing turbines manufactured in the respective years. These also would have produced power at a net additional expenditure of heat chargeable to power of 4,000 Btu per kilowatt hour. As it was, this amount of capacity was installed during these years in condensing turbines having a heat consumption of more than three times this amount. In other words, industry is providing us with a heat sump into which we can discharge our waste heat profitably instead of discharging it into the rivers, but we are not now utilizing this sump.

The successful utilization of this opportunity requires a considerable degree of cooperation and coordination between the utilities and the industries, inasmuch as the utilization of high pressure or mercury vapor in connection with industrial heat almost always results in more power available than can be used by the industry itself. Interconnections between the utilities and the industries will have to be made, and carefully considered contracts worked out. There are a few pioneers in this direction now; a number of jointly operated plants have been built and some are in operation. It seems that this offers an opportunity for us as engineers to assist in taking steps that will have a greater effect upon the conservation of resources and reduction of costs than almost any other line of endeavor we can now pursue in the power plant field.

**P. L. Alger:** This paper stresses the importance of further improving the efficiency of large central stations. The possibilities yet open in this direction through the reduction of the power losses in the boilers, turbines, and generators may be brought out in an interesting light through consideration of Figs. 3 and 6. These two figures indicate that for an average fuel cost of 6 million Btu per dollar, a reduction of 13 per cent in the station heat rate justifies an increased investment of $11 per kilowatt of capacity.

The efficiencies of typical boilers, turbines, and alternators for 75,000-kilowatt single-cylinder turbine units at the present time are approximately 85 per cent, 82 per cent, and 98 per cent respectively. The corresponding first costs of the equipment may roughly be taken as approximately $20, $8, and $4 per kilowatt of capacity.

These figures indicate that, if all the losses in the boiler could be eliminated, making it 100 per cent efficient, it would be worth 165 per cent of its present cost. Similarly, if the turbine could be made to have 100 per cent efficiency, it would be worth nearly 290 per cent of its present cost, and the alternator would be worth 140 per cent of its present cost.

The conclusions to be drawn are that in all three items of equipment the increased value to be obtained from higher efficiency warrants intensive further study by designers, but that the greatest possibilities exist in the turbine. Especial weight should, therefore, be given to efficiency when the design and selection of a turbine are being considered.

**A. C. Flory:** We note in Fig. 2 that the Edison Illuminating Company of Boston has reduced its coal consumption from 5.2 lb per kwhr in 1892 to about 1.1 lb per kwhr in 1932, or a reduction of approximately 80 per cent. Alongside this figure the increase in steam pressures and temperatures is shown, being an increase from about 350 lb saturated steam to pressures of 1,300 lb and 750 deg F. Of course, all of this reduction in coal rate is not accounted for by the change in the steam cycle itself. Roughly, the higher thermal efficiency of the more recent cycles would account for approximately 50 per cent of the decrease in specific coal consumption. There is little mention made of the fact, that since 1892 much higher condenser vacuums are common and that turbine and boiler efficiencies have advanced considerably. It should also be borne in mind that with interconnected stations and with more thought being given to the matter of flatter load curves, some advantage has been gained from that angle.

**A. H. Markwart:** The conclusions of the authors agree with the experiences of the Pacific Gas and Electric Company. The decision of this company to install high pressure units at Station A was made after a careful study had shown that such units would cost no more than for moderate pressures and there would be a marked gain in efficiency. It was not believed that maintenance and operating costs would be any higher and to date this has been true. Thirty years' experience with high head water power plants operating at pressures up to 1,000 lb has been excellent and indicated that some of the advantages of high head water power as against low head might hold for high pressure steam. This also has been confirmed by experience.

It has been feared by some operating men that a high pressure plant which operates entirely to supplement a hydro supply would be too complicated and inflexible for such service. However, experience has shown just the reverse to be true, and that a high pressure plant has marked advantages for such service.

**S. L. Pearce:** Curves are given in the paper to show the reduction in heat rate with increase in initial steam temperature and pressure, respectively, these being based on the reheat cycle. In my Presidential Address to the Junior Institution of Engineers I gave curves of a somewhat similar nature in Fig. 1, which showed variation in adiabatic heat drop with variation in steam pressure and temperature, and these curves tended to point out conclusively that increase in steam temperature gave a steady and almost constant increase in adiabatic heat drop, whereas increase in pressure did not show the same steady increase, which pointed to the fact that increase in temperature was a more important factor than increase in pressure.

The curves given in the paper do not appear to point out this factor so conclusively. For example, taking a constant pressure of 600 lb per sq in. the reduction in heat rate given by increasing the initial steam temperature from 750 deg F to 1,000 deg F is about 8½ per cent, whereas the increase in adiabatic heat drop given in my address for a similar variation is about 15 per cent. Again, assuming a constant steam temperature of 850 deg F, the reduction in heat drop by increasing the initial steam pressure from 600 lb per sq in. to 1,200 lb per sq in. is about 5½ per cent, whereas the increase in adiabatic heat drop given in my address for a similar variation is about 5 per cent.

It is appreciated that the two sets of figures cannot be strictly compared in that the problem is complicated very considerably according to the exact heat cycle adopted and the efficiency of the plant, yet one would have expected to have found a more general tendency to agreement than is demonstrated by Figs. 1, 2 and 3.

The curves for improvement in non-reheat cycle stations by increasing the steam conditions from 600 lb per sq in. 850 deg F to 1,200 lb per sq in. 1,000 deg F show a reduction in heat rate of about 9¾ per cent. The increase in adiabatic heat drop between these two conditions is, however, about 14 per cent.

As pointed out above, the foregoing figures are not strictly comparable, but the main point is that the figures in the paper do not seem to illustrate so clearly the advantage of temperature as compared with pressure in improving thermal efficiency.

I observe with interest the statement that: "Station designs in which one steam generating unit supplies all of the steam required by one turbo generator unit are becoming more and more generally accepted as the most economical," but I cannot trace having seen any convincing argument supported by comparative figures to prove this contention.

I do not agree with the statement that the availability of steam generating units and turbo generating units is about the same, as our experience would appear to show that the outage time for boiler plants is considerably greater than for turbine units. This is an argument against the suggestion of arranging the boiler plants individually for the turbine units.

Reference is made to the control of the superheat temperature, but it can be said that in England it has been found possible, by arranging the superheater so that it derives its heat partly by convection and partly by radiation, to obtain a very flat total temperature characteristic with variation in load. Variation in steam temperature with "dirtying up" of the boiler merely is a question of making suitable arrangements for cleaning the superheater surface and the surface of the boiler in front of the superheater satisfactorily during operation. Properly designed soot blowers operated carefully with reference to the temperature indicating equipment provided on the boiler plant make it possible to maintain a comparatively constant steam temperature.

**Charles H. Merz:** We are very much in agreement with the statements in the paper as regards the increased efficiency obtainable by higher superheat temperatures, and recognise that there are greater possibilities in this direction than by further increase in pressure. Our figures for the advantage obtained from higher pressures, however, seem to show rather lower savings, possibly due to greater allowances for the extra feed pump energy required and for the decrease in the average stage efficiency of the turbine as the pressure is increased.

There is a strong tendency in England, at the present time, not to go beyond 600 lb per sq in. and it is interesting to know that the authors consider that the use of higher pressures would not necessarily increase the capital cost of the station. This must, of course, be due to the fact that in America the design of high pressure installations has been fairly well established, whereas in this country we should be faced with considerable extra development charges at the outset.

We are just bringing into operation two new 600-lb pressure plants at Dunston on the northeast coast, and at Barking in the London area, the initial temperature in each case being 800 deg F. The former station has flue-gas reheat to the initial temperature. Judging from the contract prices it looks as if the adoption of reheat has had very little effect in increasing the capital cost when full allowance is made for the saving in steam consumption, and the consequent reduction in boiler and condensing plant.

The question of obtaining the maximum capacity from a given turbine shell is mentioned in the paper. It is interesting to note that by the adoption of reheat to the initial temperature the maximum capacity from the same turbine exhaust can be increased by something like 20 per cent without increasing the percentage leaving loss.

**A. McKinstry:** The desirability of utilizing higher steam pressures and temperatures together with interstage reheating and re-generative feed heating, has been appreciated by engineers for many years past and there has been a continued effort towards development in this direction. It is notable that the means adopted for attaining these ends has not been uniform throughout the world, the tendency in the United States being to utilize high pressures and moderate steam temperatures in the earlier schemes, while in Europe the line of development has been higher steam temperatures and moderate pressures. This is particularly instanced by the authors' statement that new stations are now being built in the United States using steam at temperatures from 825 to 850 deg F.

A power plant on a commercial scale using a steam temperature of 842 deg F with a pressure of 800 lb per sq in. was installed in Europe 7 years ago and there are as many as 23 stations in commercial operation at the present time with temperatures ranging between 825 to 842 deg F.

At the St. Denis Station of the Societe d'Electricite de Paris, boilers are just going into operation using a steam temperature of 878 deg F, while in London the first of the boilers at the Battersea Station of the London Power Company are ready for steaming, these boilers providing steam at a temperature of 875 deg F.

The authors have given figures for comparative economies made available by the use of increased steam pressures, and in the light of experience on this side of the Atlantic, 13½ per cent saving, when comparing a 1,200 lb per sq in. 850 deg reheat cycle station with a 400 lb 850 deg straight cycle station, appears to be rather optimistic, under normal working conditions, although apparently possible on theoretical grounds.

Mention is made of the progressive favor with which the one boiler per turbine arrangement is received in the United States. Possibly this position arose from the use of large base load stations in the United States where grid distribution of power has been developed to a very wide extent. In Europe, the one boiler per turbine arrangement is not now received with so much enthusiasm, and there is a distinct return to favor of the two boilers per turbine arrangement. The large amount of capital lying unproductive when large single boiler and turbine units are out of commission for any purpose is viewed with much disfavor by power engineers in Europe.

Reference is made in the paper to the development of the series boiler and illustrations of coil type boilers are given. So far in Europe the coil type boiler has not met with the success expected for it in some quarters, although series boilers of the type in which forced flow steaming economizers work with natural flow steam generating banks and large water-cooled furnaces have proved quite successful in service.

**I. V. Robinson:** Undoubtedly the higher pressures and higher temperatures do result in a reduced heat consumption per unit generated and also the capital cost of the plant is likely to be reduced as greater experience is gained with this type of apparatus. However, I question very strongly the advisability of attempting to balance so closely the charges due to extra capital expenditure against the savings due to improved efficiency. In the paper a 40 per cent load factor is assumed in order to balance these two items, but it is not known with any degree of accuracy what the load would be. When a new unit is set to work it usually gets the pick of the load and runs a very high load factor. It may thus take the load from an older unit which has not been installed very long and which is still very efficient. As a result this older unit may not get anything like 40 per cent load factor. In its turn the favored unit is superseded by another and so on. I doubt very much whether any unit in any generating station in the world will average a 40 per cent load factor over a period of 15 years. When there is this quite unknown factor of the use to be made of the machine is it really of any value to balance to a nicety the capital charges against running costs?

Then again, on the generating side of the problem we have certainly got into an area where the law of diminishing returns becomes effective. When a station with a heat consumption of less than 20,000 Btu per unit generated was a station of which the engineer could be proud there was plenty of room for improvement, but now when there are so many stations running down to 14,000 Btu the further possible advantage is really very small.

In considering the total price that the consumer has to pay for the units he gets in his radiator, etc., the generating costs are an insignificant amount and the reduction in cost due to 5 per cent or even 15 per cent improvement in thermal efficiency would be so slight that it is doubted if the purchaser would see any difference at all in his bills.

It seems that this constant striving after thermal efficiency is of greater interest to the engineers in charge, it becomes a matter of personal pride to get the lowest possible figures, but that it is a matter of negligible interest to the man on whom they all depend, *i.e.*, the consumer. If the brains which have up to now been used mainly, if not entirely, to reduce the generating costs, were able to do equally effective work as regards distribution then the purchaser would be interested, the cost of electricity would be reduced and the use would be increased enormously.

Although putting forward this view I appreciate the fact that it seems extremely difficult to find a point in the distribution system upon which a successful attack for the reduction in cost can be launched. We have gone through exactly the same phase of development in the power station. Up to a certain period the major efforts to reduce generation cost were confined to the turbine house, the boiler house being left as a somewhat dirty and undesirable area into which the engineers did not desire to intrude. Later the engineers extended their activities to the boiler house with the result that it has become a different place entirely and quite as efficient as the turbine house. Could not the same engineers now consider the distribution system? Possibly the solution may be the introduction of some simple form of transformer, perhaps a thermionic valve or some such device which could be installed on the purchaser's premises and would transform comparatively high tension current to the pressure required for domestic appliances.

**W. E. Wellmann:** German opinion is not against high pressure nor high temperature in any way. This can be proved by some stations in Germany using the one or the other. But the application depends largely on the especial conditions encountered.

It may be interesting to use high pressures up to 120 atmospheres in the case of an industrial plant with high consumption of process steam and high load factor, while on the other hand for a peak load generating station a pressure of only 30 atmospheres still is justified today.

One of the great difficulties that concerns the use of temperatures of 450 deg C and higher is the difficulty of obtaining suitable material; this difficulty still is so serious that the combination with high pressures does not seem very desirable at the present because it complicates the task of the designing and operating engineer. This has to be considered the more since ". . . the design and manufacture of high pressure generating equipment is in its infancy."

It is disadvantageous that the size of the turbine (kw) is chosen by the customer and the shell size by the manufacturer. I believe that in the near future standardization will be of help.

We agree with the conclusion in the paper that high pressure and high temperature have to be taken into consideration in every case of new installation of generating equipment.

**M. D. Engle and I. E. Moultrop:** The X ray has been an invaluable tool in the development of high pressure equipment from the very start and the discussions have shown the important part it is expected to play in future developments. No doubt the development and acceptance of welded pressure parts, inspected by means of the X ray will do much to accelerate the adoption of the higher pressures in the future and at the same time will aid in the manufacture of better and cheaper equipment for moderate pressures.

It is indeed encouraging to see such general acceptance of the results obtained in the earlier high pressure installations. We believe that a valuable lesson can be learned from this experience. Those responsible for the high pressure and high temperature installations have been very frank in discussing publicly their troubles and the means employed for overcoming the operating difficulties that have arisen. This frankness has engendered confidence in the reports and has resulted in a more rapid adoption of the higher pressures and temperatures than otherwise would have been possible.

Great credit is due the manufacturers of the equipment used for the capable manner in which they have executed their difficult tasks and for their willingness to have the troubles discussed so frankly in our technical meetings. We feel that they also have been benefited by this policy.

No doubt, in the future, we shall see many more full service installations where the electric utility will supply to the industries both electrical energy and steam for process. Such arrangements are so basically sound, where they are geographically possible, that we can expect rapid development along this line during the next business cycle. A frank public discussion of the problems arising and the solutions found will aid materially.

We were particularly pleased with the discussions submitted by our fellow engineers in Europe. It is very apparent that our ideas do not exactly coincide in the solution of the major problem of generating electrical energy at a lower cost. This makes their discussions doubly valuable. European engineers in general favor higher temperatures at moderate pressures while American engineers favor higher pressures at moderate temperatures. Actually, pressures and temperatures go hand in hand. The apparent lack of suitable materials of construction has held back the adoption of higher temperatures in the United States but European engineers have gone ahead and have outstripped us in this respect. Recent installations indicate however that American practise rapidly is catching up in the use of the higher temperatures. These installations are employing the higher pressures also.

The advisability of the one boiler per turbine idea has been questioned. The excellent papers by Hirshfeld and Moran on the reliability of large boiler units are the basis for the general acceptance of this fundamental in the United States. We believe that the idea is so sound that it will be accepted universally in the very near future.

In reply to those who have suggested that we should turn our efforts toward reducing the cost of transmission and distribution we would point out that this phase of the problem is receiving just as intensive study as the development of the generating stations. It is felt that the electrical engineers are waging just as courageous and just as successful a fight as the mechanical engineers. The American Institute of Electrical Engineers already has placed on record its accomplishments in transmission and distribution, and the battle still goes on unabated.

Electrical pressures have been raised from 115-230 volts to 220,000 volts. Cables have been developed so that today we are able to pull a 700,000-cir mil 14-kv three-conductor cable into the same duct formerly filled by a No. 4/0 14-kv cable. The quality has been improved with consequent reduction in failures, and due to lower losses, greater capacity can be delivered by a modern cable than by obsolete types of the same size and at the same voltage. Further advances have been made through the installation of low-voltage a-c networks, which probably will ultimately supersede the d-c systems, and the adoption of 4,000/2,300-volt a-c networks in suburban districts.

Electrical substations have been going through the same intensive developments. Better designs have resulted in speedier and more reliable breakers and more dependable protective devices. Large power transformers are now designed to give efficiencies as high as 99.60 per cent. These higher efficiencies and this greater reliability have been obtained at a lower cost, when all factors are considered. They are all doing their part in reducing the cost of the service, and this is being done in spite of the constant demand for better and more reliable service.

The battle for better service at lower cost is being waged on all fronts and is not being confined to any one sector.

# Recent Actions Taken By the Symbols, Units, and Nomenclature (S.U.N.) Committee

## Of the International Union of Pure and Applied Physics (I.P.U.) in Reference to C.G.S. Magnetic Units

BY ARTHUR E. KENNELLY*

Fellow and Past President of the A.I.E.E.

***Synopsis.**—In reference to the C.G.S. magnetic units, a brief historical outline is presented of the actions taken by international electrical congresses from 1893 to 1904, and by international technical and scientific unions from 1904 to 1932. Emphasis is laid on the results of the S.U.N. Committee meeting of July, 1932, as the latest development.*

*The present status of international agreement on C.G.S. magnetic units is unofficially presented, in the light of the historical background.*

*Turning to future possible developments, certain questions are pending for consideration, by either or both committees, in order to clear up any outstanding differences of international opinion over magnetic units in the classical C.G.S. system.*

*In order to convert the existing series of practical electromagnetic units (ohm, volt, ampere, coulomb, farad, joule, watt, henry and pramaxwell) into a complete system, international agreement must first be reached upon the two outstanding questions:*

*(a) Subrationalising ($4\pi NI$ or $NI$ for mmf).*

*(b) The unit of length to be adopted (meter or cm). Suggestions are offered along both these lines.*

### PURPOSE AND SCOPE

THE aim of this paper is to offer a brief unofficial account of what international actions have recently been taken in the matter of C.G.S. magnetic units, tending to eradicate some of the ambiguities that have pervaded magnetic literature during the last thirty years, and especially the actions in this direction taken during 1931-1932, by the International Electrotechnical[17] Commission (I.E.C.) and by the International Physical Union (I.P.U.), together with the present nomenclature status of these C.G.S. units, and what little yet remains to be done, in order to secure general international agreement. It will be seen that this is essentially a matter of names, definitions and nomenclature; since no changes have been suggested in the C.G.S. units themselves.

The second part of the paper relates to magnetic units in the practical, or *volt-ohm-ampere* series. Here relatively little has yet been accomplished. In order to extend this series into a complete comprehensive system, it appears to be necessary to secure agreement upon two very important questions: (1) Shall the mmf of a coil of $NI$ ampere-turns be $4\pi NI$ practical units, or $NI$ ampere-turns simply? (2) What unit of length shall be embodied in the system? Suggestions are advocated upon both questions.

### HISTORICAL OUTLINE SINCE 1927

In a paper entitled *Magnetic-Circuit Units,* read before the Midwinter Convention of the A.I.E.E., January 29th, 1930, the writer had the privilege of presenting a historical outline of magnetic units from 1861 up to that date. It will therefore not be necessary here to reconsider the history of the subject prior to 1927, when the International Electrotechnical Commission (I.E.C.) prominently entered the field.

The I.E.C. was projected in 1904, at the International Electrical Congress of St. Louis, and was inaugurated at London in 1906. It has been continuously in existence since that time. It has national committees in some twenty countries. Each such national committee is composed of representatives of its national government, local scientific and technical bodies, as well as various electrical industries. The general secretariat is in London; but the presidents, of which there have been eight up to this date, are elected successively from the various countries. Each national committee has its own president, secretary, and other officers.

The work of the I.E.C. is divided among nineteen separate advisory committees, each with its own president, and with a secretariat located in one country. Some advisory committees have delegates from a relatively small number of countries. Others have delegates from all or nearly all countries. Through the London central office, the different advisory committees convene at suitable times and places, to work out their own problems. As and when they arrive at agreements, they notify the central office, and report to the next plenary meeting of the I.E.C. as a whole. The plenary meetings are held about once in two years, and there have been nineteen in all thus far, distributed in time and place among twelve cities. The work of a plenary meeting consists largely of receiving reports from the various advisory committees, and of adopting them, as a body, by vote. The I.E.C. also receives and passes upon applications for the holding of international electrical congresses, in countries which desire to hold them.

The tasks undertaken by the various advisory committees relate broadly to electrical engineering, and

*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

especially to the standardisation of machinery, apparatus, specifications, methods and tests entering into electrical applications. In advisory committee No. 1 on "Nomenclature," definitions, symbols and units have been dealt with at various times.

At the plenary meeting of 1927, in Bellagio and Rome, a proposal was introduced by the Italian national committee, relating to magnetic units; both C.G.S. and practical. After some unsuccessful discussion, it was referred to a special subcommittee on "Magnetic Units" of the Advisory Committee on Nomenclature, for study and report, with a personnel group of representatives from seven countries. This subcommittee worked over the subject until 1929, without being able to reach an agreement, owing to the marked differences of opinion presented among the various national committees involved. The subcommittee reported in 1929, recommending that, in view of the large range of differences in opinion, the subject should be discussed in the national committees and placed upon the agenda for the next plenary meeting at Oslo in 1930. The subject was, in fact, ventilated in the technical press of several countries, in advance of the meeting of 1930.

The main difficulties in reaching agreement centered around the unit[3] name *gauss*, which had been adopted in 1900, at Paris. Magnetic literature all over the world, between 1900 and 1930, showed much confusion and ambiguity as to the meaning of this name. Some writers used it exclusively for the unit of flux density, or induction density $B$. Others used it exclusively for the unit of magnetising force, or magnetic intensity $H$; while yet others used it for both $B$ and $H$ indiscriminately. Moreover, some authoritative text books held that the quantities $B$ and $H$ were physically different, in which case, of course, the unit name *gauss* could only be applied to one; but to which was not certain. Other equally authoritative text books held, on the contrary, that the quantities $B$ and $H$ were physically identical; so that the *gauss* if applied to one, would also be applicable to the other. There was no middle ground between these two positions, and the first aim of the international subcommittee dealing with the subject, was to decide which of the two contentions should be supported.

When the magnetic units subcommittee met (June, 1930) in Scandinavia, its numbers were increased to include twelve countries, and its name was changed to Section B of the Nomenclature Committee, dealing with Electric and Magnetic Magnitudes and Units, (E.M.M.U.). After discussion, it was voted unanimously to adopt the convention, that for electrotechnical purposes, the quantities $B$ and $H$ should be regarded as being physically distinct; so that in a vacuum, or free space, $B = \mu_o H$, where $\mu_o$ is the *space permeability*, and is not a mere number, but a physical quantity having dimensions; furthermore that in the case of magnetic substances, $B = \mu H$, where $\mu$ is the *absolute permeability* of the medium, with the same dimensions as $\mu_o$; but the relative permeability of the medium would be $\mu / \mu_o$, a mere number.

These conventions having been adopted, the E.M.M.U. committee was able to deal speedily with other C.G.S. magnetic units which had offered difficulty. The following list of units and names was agreed to, either unanimously or by considerable majorities.[4]

(a) For the C.G.S. Magnetic Unit of magnetic flux $\Phi$, the name *maxwell*

(b) For the C.G.S. Magnetic Unit of flux density $B$, the name *gauss*

(c) For the C.G.S. Magnetic Unit of magnetising force $H$, the name *oersted*

(d) For the C.G.S. Magnetic Unit of mmf $\mathcal{F}$ the name *gilbert*.

The name *maxwell* had already been adopted in 1900 at Paris, for magnetic flux $\Phi$, as reaffirmed here under (a). The name *oersted* was applied to the unit of $H$, partly to indicate that, by convention, the name *gauss* being assigned to the unit of $B$, was not applicable to the unit of $H$. In America, the name *oersted* had been applied provisionally to the unit of reluctance $\mathcal{R}$, since 1900; but without international authorisation. The assignment of the name *oersted* to the unit of $H$ as in (c), leaves the C.G.S. magnetic unit of reluctance without a name, for the present.

The E.M.M.U. Committee also adopted the name *pramaxwell* for the unit of magnetic flux $\Phi$ in the practical series ($10^8$ *maxwells*) and the prefix *pra* as a general means of designating a practical unit derived from a C.G.S. unit.

The preceding resolutions, and others not directly within the scope of the C.G.S. units, were reported to the plenary convention of the I.E.C. at Oslo, and by it unanimously adopted, July 9th, 1930.

Following upon the publication of the I.E.C. actions on the C.G.S. magnetic units, comments appeared in the scientific and technical press of various countries. In general, these comments were favorable; but some adverse criticisms also appeared, mainly directed to two points:

(a) That names of savants should not have been given to C.G.S. units.

(b) That the name *gauss* should not have been given to the unit of $B$; but to that of $H$, in conformity with the usage of terrestrial magnetic observatories.

In regard to (a), the Paris Congress of 1900 had assigned the names *maxwell* and *gauss* to C.G.S. units, in view of the decision of the Congress of 1893, at Chicago, that working magnetic units should be kept within the C.G.S. system.

In regard to (b), it was pointed out that in view of the confusion in literature over the use of the name *gauss*, the I.E.C. convention necessarily brought embarrassment to some group of workers; but that the number who were in the habit of using the *gauss* for $B$ seemed to be much greater than those accustomed to using the *gauss* for $H$. Moreover, the earth's magnetic field is measured in air, which being a feebly magnetic medium, may be regarded as developing a flux density $B$ under the action of the magnetic intensity $H$ although, from a numerical standpoint, there would be no appreciable difference between the air values of $H$ and $B$. Terrestrial magnetic observatories are also accustomed to report their magnetic measures in terms of a special unit the *gamma* or $\gamma$, equal to $1/10^5$ *oersted*, and there had been no suggestion of disturbing this usage.

In view of any or all differences of opinion elicited by the publication of the I.E.C. Oslo resolutions, arrangements were made and announced early in 1931, to hold a special meeting of the E.M.M.U. committee at London, in September 1931, to review these C.G.S. recommendations.

## ESTABLISHMENT OF THE S.U.N. COMMITTEE BY THE INTERNATIONAL PHYSICAL UNION

The International Union of Pure and Applied Physics (I.P.U.), met at Brussels in July 1931, and established for the first time, an international committee on "Symbols, Units and Nomenclature," (S.U.N.). The S.U.N. committee elected as its Chairman Sir Richard Glazebrook, and as its Secretary, Dr. E. Griffiths. Since electro-technical units fall within the scope of the S.U.N. Committee, the I.E.C. extended an invitation to the I.P.U., to aid in the task of seeking international agreement on electric and magnetic units, through the coöperation of the S.U.N. and E.M.M.U. committees. This invitation was accepted, and the S.U.N. Committee was invited to have its members attend and take part in the London E.M.M.U. meeting, already scheduled for September 1931. The S.U.N. Chairman and Secretary were able to attend, and also the General Secretary of the I.P.U., Professor H. A. Abraham.

## ACTIONS OF THE LONDON MEETING OF E.M.M.U. COMMITTEE, SEPTEMBER 1931

At the opening of the E.M.M.U. meeting in London, September 18th, 1931, the President of the I.E.C., Dr. A. F. Enström, and the General Secretary, Mr. C. LeMaistre, took part.[17] The national committees of ten countries were represented:—Denmark, France, Germany, Great Britain, Holland, Italy, Norway, Poland, Sweden and U.S.A.

The agenda proposed by the American committee in February 1931, were then adopted as basis for procedure.

The first proposal on these agenda: (1a) was considered:

> "that the C.G.S. magnetic units and their accepted names, as fixed at the Oslo plenary meeting, should remain undisturbed"

This proposal was voted unanimously, two countries, however, abstaining, (Holland and Italy).

The next proposal (1b), related to a series of *practical* magnetic units, based on the *pramaxwell*, or *volt-second* as adopted at the Oslo meeting, with the *ampere-turn* as unit of mmf. After a long discussion, during which considerable difference of opinion was revealed, it was voted to defer action on these practical units until the national committees should have had further opportunity of examining the question.

On the particular question, however, of a practical unit of mmf $\mathfrak{F}$, and whether a coil of $N$ turns, carrying a steady current of $I$ amperes, should be taken as $\mathfrak{F} = 4\,\pi\,(NI)$ units, or merely $\mathfrak{F} = (NI)$, a vote was called for on the proposition that it should be $\mathfrak{F} = 4\,\pi\,(NI)$. Three countries were in favor of the proposition (France, Holland and Italy); while four voted against the proposition: (Germany, Great Britain, Sweden and U.S.A.). Two countries, Norway and Poland, abstained from voting. It is evident that there is much difference of opinion over this important question.

Item II of the agenda, on a conventional interpretation of reactive power in unspecified, alternating-current right-angle triangles, was next considered; *i.e.*, whether $+\,j$ *vars* should be taken as signifying inductively reactive power, or the reverse, when the basis of the diagram is not specified.

It was unanimously voted that a convention should be adopted; but that decision as to the direction, should be deferred until a new and definite American recommendation should be presented.

Some difference of opinion had been raised as to whether the particular direction recommended in the agenda ($+\,j\,P_r$ for inductively reactive power), was the more advantageous choice.

Item III of the agenda related to a proposed international adoption of the prefixed "*ab*" and "*stat*," applied to a practical unit, for the designation of a corresponding unit in the C.G.S. magnetic, or in the C.G.S. electric system, respectively. These prefixes have been and are in use, to some extent, in America; but have never been internationally adopted.

For lack of support to the proposal, no action was taken and the meeting adjourned.

## MEETING OF THE S.U.N. COMMITTEE IN PARIS

The S.U.N. Committee issued a questionnaire,[19] in December 1931, to physicists and physical societies in different countries, on "Electrical Units," calling attention to certain ambiguities in the definitions of fundamental electric and magnetic quantities entering into the C.G.S. system, and inviting opinions as to how these ambiguities might be eliminated, in order to arrive at international agreement. The replies to this questionnaire were collected. In view of the considerable number of physicists assembling in Paris during the week July 5th-12th, to attend the International Electrical Congress of 1932, the S.U.N. Committee called an informal meeting in Paris on July 9th, to discuss these questions, and especially the C.G.S. magnetic units.

The meeting was held under the chairmanship of Sir Richard Glazebrook, Dr. E. Griffiths of the British National Physical Laboratory (N.P.L.) being the Secretary. Nineteen persons, from eight countries, attended. The actions taken were informal, in the sense that the voting was not by countries; but by individuals.

The following propositions were adopted, either unanimously, or by considerable majorities:

1. Any system of units recommended must retain the eight internationally recognised practical units: *joule, watt, coulomb, ampere, ohm, volt, farad, henry.*
2. The C.G.S. system of units is suitable for the physicist.
3. A system of practical units including the above eight quantities, is derived from these by multiplying the C.G.S. unit by appropriate powers of 10.
4. That M. Abraham at the request of the conference, should prepare for consideration by the Commission, a preliminary report on the fundamental units.
5. The system of magnetic units may be based on the following two methods as alternatives:
   (a) The force between two elementary magnet poles, (Coulomb).
   (b) The force between two elements of current, (Ampère).
6. $B$ and $H$ are quantities of different nature.
7. The factor $4\pi/10$ should be retained in the definition of magnetomotive force.

The following table of electromagnetic quantities, which in accordance with suggestions received, has been revised since the meeting, is now proposed for adoption by the British representatives.

TABLE I—ELECTROMAGNETIC QUANTITIES

| Quantity designated | Symbol | C.G.S. units<br>Equation | <br>Name | Volt-ampere units<br>Unit | <br>Defining units |
|---|---|---|---|---|---|
| Flux | $\Phi$ | $\frac{d\Phi}{dt} = -E$ | Maxwell | $10^8$ maxwells | Volt-second |
| Induction or flux density | $B$ | $\int B \,.\, dS = \Phi$ | Gauss | $10^8$ gauss | Volt-sec/cm$^2$ |
| Mmf round a circuit | $F$ | $F = 4\pi NI$ | Gilbert or oersted-cm. | $\frac{1}{10}$ gilbert or<br>$\frac{1}{4\pi}$ ampere-turn | Amperes |
| Magnetizing force or field strength | $H$ | $\int B \,.\, \cos\epsilon \,.\, ds = F = 4\pi NI$ | Oersted | $\frac{1}{10}$ oersted or<br>$\frac{1}{4\pi}$ amp turn per cm | Amperes per cm |
| Permeability | $\mu$ | $\mu = \frac{B}{H}$ | Permeability | $\frac{10^9 \text{ gauss}}{\text{oersted}}$ | $\frac{\text{Volt-sec/cm}^2}{\frac{1}{4\pi}\text{ amp turn/cm}}$ |

## PRESENT STATUS OF THE C.G.S. MAGNETIC UNITS AS THE RESULT OF I.E.C. AND I.P.U. ACTIONS

It will be seen from the preceding S.U.N. recommendations and table, that there is agreement in all essentials between the findings of the I.E.C. and I.P.U. committees, so far as concerns the C.G.S. magnetic units. Both have recommended the convention that the quantities $B$ and $H$ should be taken as different, and that the unit names *maxwell, gauss, gilbert* and *oersted* for $\Phi$, $B$, $\mathcal{F}$ and $H$ are respectively satisfactory. If these conventions continue to receive support, the ambiguities and confusion which have pervaded international magnetic literature during the past thirty or forty years, should disappear. The only group whose current practise seems to be embarrassed by the conventions, is the terrestrial magnetic group, who have long been accustomed to employ the *gauss* for $H$. As has already been pointed out, however, these important scientific researches in terrestrial magnetism deal almost exclusively with magnetic phenomena in air, at ordinary temperatures and pressures. The numerical difference, between $B$ and $H$ in air under such conditions, is admitted to be only about one part in three millions; which is insignificant in the existing stage of measurement precision in terrestrial magnetism. There can be no present confusion in magnitudes, when the *gauss* in air is mentioned. Moreover the use of the *gamma* in terrestrial magnetic work is not interfered with.

In the United States, The I.E.C.-I.P.U. Conventions have been accepted by the National Bureau of Standards, the Society for Testing Materials, various committees of the A.I.E.E., and the U.S. National Committee of the I.E.C. Endorsements have appeared in electrotechnical journals. They are also used, to the exclusion of all others, in the "Report on Proposed American Standard Definitions of Electrical Terms,"[33] sponsored by the A.I.E.E., and recently published (August 1932). Up to the present date (November 1932), no objections seem to have appeared in North American literature to the I.E.C.-I.P.U.-C.G.S. conventions, and the only complaints raised have been that the previously existing C.G.S. unit name for reluctance has been removed, without designating any substitute. As a minor detail of symbology, however, an objection has been raised to the use by the I.E.C. of the symbol $\mu_o$ for space permeability. This symbol has been used to some extent in America for "initial permeability;" *i. e.*, the "normal permeability when both the magnetising force ($H$) and the induction ($B$) are vanishingly small." If it should be desired to retain the symbol $\mu_o$ for initial permeability, space permeability, or the permeability of vacuum, might be represented by some other symbol, such as $\mu_r$.

### MATTERS OUTSTANDING FOR CONSIDERATION IN RELATION TO C.G.S. UNITS

Up to this point in the paper, the writer has endeavored to present an unbiased historical picture of what the I.E.C. and I.P.U. have been able to do for clearing international understanding of magnetic unitology. In what follows, opinions and suggestions are submitted, in the role of an advocate rather than of a historian.

It is often supposed that the well known relation $B = \mu H$ *gausses*, which connects magnetic flux density with permeability and magnetising force, extends only to magnetic media, and has neither theoretical nor practical interest when free space, or non-magnetic media, are considered. Further examination shows, however, that this is too narrow a view to fit the facts. In a vacuum, free space, or non-magnetic media, the equation becomes $B_o = \mu_o H$ *gausses*; where $B_o$ is the space flux density, and $\mu_o$ the space permeability. In the C.G.S. magnetic system, the numerical value of $\mu_o$ is arbitrarily made equal to unity, and for purposes of mere computation, the equation might just as well be $B = H$, in which form it sometimes appears in text books and which would justify the view that $B$ and $H$ are physically identical. But in the C.G.S. electric system (commonly called the electrostatic system), the value of $\mu_o$ necessary to satisfy the equation is $\mu_o = 1/c^2$, where $c$ is the velocity of electromagnetic wave propagation, or nearly $3 \times 10^8$ meters per second. In any other system of electromagnetic units, a value of $\mu_o$ differing from unity must be used, even for purposes of computation, except in the Maxwell Q.E.S. (quadrant-eleventh gram-second) system. A few cases appear in the following table:

TABLE II

Values of $\mu_0$ Satisfying the Space Relation $B_0 = \mu_0 H$ for Various Systems

| No. | System of units | Value of $\mu_0$ |
|---|---|---|
| 1 | Classical or Maxwellian C.G.S. magnetic unrationalised | 1.0 |
| 2 | Classical or Maxwellian C.G.S. electric unrationalised | $1/(0.9) \times 10^{-21}$ |
| 3 | M.K.S. (meter-kilogram-second) unrationalised | $10^{-7}$ |
| 4 | M.K.S. (meter-kilogram-second) rationalised | $4\pi \times 10^{-7}$ |
| 5 | C.G-S.S. (cm-gram-seven-second) unrationalised | $10^{-9}$ |
| 6 | C.G-S.S. (cm-gram-seven-second) rationalised | $4\pi \times 10^{-9}$ |
| 7 | Maxwellian Q.E.S. (quadrant-eleventh-gm-second) unrationalised | 1.0 |

It has been pointed out in several countries that there are several classical C.G.S. magnetic formulas which should include $\mu_o$, in order to acquire general application. One of these is $B_o = \mu_o H$, often written $B = H$ for nonmagnetic media. This question of inserting $\mu_o$ in certain classical C.G.S. magnetic formulas where it generically belongs, ought to be considered by the E.M.M.U. Committee, independently of the I.E.C. Convention that $\mu_o$ has dimensions of some kind, other than a mere number. It has been claimed that $\mu_o$, as space permeability, is a fundamental physical constant. The Ausschuss für Einheiten und Formelgrössen has named it the "Induction Constant."

### QUESTIONS TO CONSIDER IN RELATION TO THE PRACTICAL UNITS

It will probably be generally admitted that the difficulties in the way of rectifying the C.G.S. magnetic units internationally are small compared with the difficulties of reaching agreement over the extension of the practical series of units into a complete comprehensive system. No changes have been made in the classical C.G.S. Magnetic system, which was adopted by the Paris Congress of 1881, endorsed, beyond any question of modification, by the Paris Congress of 1900, accepted by the Electrical Committee of the International Committee of Weights and Measures and was also endorsed by the S.U.N. Committee at the Paris meeting last July, under item (2) above referred to. On the other hand, the practical units are now nine in number: the *ohm*, *volt*, *ampere*, *coulomb*, *farad*, *watt*, *joule*, *henry* and *pramaxwell* or *volt-second*. These form a one-to-one series; but not a complete system. We may define a comprehensive practical system as any system of units susceptible of universal scientific measurements and computations, which includes the nine practical units as constituent elements. In order to complete the practical series into a practical system, certain additions must be agreed upon. These missing elements are of great importance. The first elements of the series are now more than fifty years old, and the completed system may last for centuries. Great care is therefore needed in choosing the best new elements; because while the choice is pending, we can carry on all our work in the C.G.S. system.

### QUESTION OF PRACTICAL UNIT OF MMF AND SUBRATIONALISATION

Probably the first question to consider is the definition of the practical unit of mmf. Shall it be the $1/4\pi$th part of an ampere-turn or just an ampere-turn? This is the old rationalisation question first raised by Heaviside in the seventies. He showed that rationalised C.G.S. units would be much simpler to think with, and work with, than those of the classical C.G.S. system; although the method by which he advocated rationalising, would have meant changing the magnitudes of nearly all the existing practical units and standards, and was quite unacceptable. Later on, it became known how to subrationalise a system; *i. e.*, to obtain the advantage of rationalisation through increasing the unit of space permeability $4\pi$ times, and diminishing the unit of space inductivity $4\pi$ times.

Karapetoff has recently presented a simple means of analysing any system of electromagnetic units, (setting aside the units of length and mass), in terms of five significant constants: namely, ($n$) the ratio of electric flux to the charge producing it; ($p$) the corresponding ratio of magnetic flux to the pole producing it; ($k$) the ratio of the mmf of a coil to the current-turns producing it; ($\epsilon_o$) the space inductivity and ($\mu_o$) the space permeability. He proceeds to show that a certain simple relation must hold among these five parameters in any workable system $\epsilon_o\,\mu_o\,c^2 = \dfrac{n}{k}\cdot\dfrac{p}{k}$. The three parameters $n$, $p$, and $k$ are indicated to be arbitrary numerics; while the product $\epsilon_o\,\mu_o$ has the same dimensions as the inverse square of $c$ the light velocity. On the basis of this analysis, we may define a system as subrationalised, when the ratios $n$ and $p$ are each equal to unity. If $k$ is also unity, so much the better. In both classical C.G.S. systems (magnetic and electric), as well as in the Q.E.S. system, the ratios $n$ and $p$ are each equal to $4\pi$. This makes unit pole produce $4\pi$ maxwells, and a corresponding numerical relation between electric charge and flux; whereas the basic idea should be that unit pole is a maxwell, and a unit charge is unit flux. So great is the advantage of this simplification that, as we all know, a large part of modern electromagnetic theory is carried on in the Heaviside-Lorentz rationalised C.G.S. system, and not in the classical C.G.S. system.

Various writers have indicated the simplification in working formulas brought about by subrationalisation. The books and papers thus far written in systematised practical units (Giorgi, Bennett, Karapetoff) have used $n = p = k = 1$.

The proposition to adopt $4\pi\ NI$ as the mmf of a coil in the practical system was raised in the E.M.M.U. London meeting of September 1931. At that time, the vote was 4 to 3 against the proposition, (two countries not voting). At the S.U.N. Paris meeting of July 1932, a similar proposition was carried by a vote of 10 to 3; so that the E.M.M.U. was in favor of rationalising, by a small majority; while the S.U.N. was opposed to rationalising, by a large majority. The question should be thoroughly examined in all countries and only finally settled, one way or the other, by a large majority. There is a danger that if the vote is not nearly unanimous, there may be a schism in the practical system, just as there has already been a schism in the C.G.S. system. We should thus face the danger of having a classical practical sect and a rationalised practical sect.

The arguments raised against practical rationalisation seem to be weak. One has been that certain well known relations now existing between the C.G.S. magnetic and C.G.S. electric systems would be lost if rationalisation were adopted. Granting that this is true, there can be no bad result in the case considered, because there will be a practical magnetic system; but no practical electric system. The duality of the present classical C.G.S. system will fortunately disappear from the proposed completed practical system. It has also been urged that the product $\epsilon_o\,\mu_o$ which is $1/c^2$ in the C.G.S. system, will have some other value in the practical system, when rationalised. This may be true in the general case; but is not true in either of the proposed completed practical systems. See Table III, Nos. 6 and 8.

Table III, prepared in accordance with the Karapetoff analysis, brings a number of different systems into comparison. Nos. 1 and 2 are the classical C.G.S. systems. No. 3 is the rationalised Heaviside-Lorentz system, No. 4 is the Maxwell practical system, as drawn up by its author and unrationalised. No. 5 indicates how that system would appear if rationalised. No. 6 is the Giorgi system, in the rationalised form presented by its author; while No. 7 is how it would appear unrationalised. No. 8 is the system for which there are a number of claimants, among them Dellinger, Bennett and Karapetoff. No. 9 is the same in unrationalised form, first suggested by the Committee on Units and Standards of the A.I.E.E. in 1891; although the implications as to the unit of mass ($10^7$ gm) were not then apprehended.

It has always been urged against rationalisation that if the factor $4\pi$ is taken out of mmf it will have to be inserted in permeance and reluctance in order to maintain the magnetic flux $\Phi$ unchanged in magnetic-circuit Ohm's law. The argument is that no advantage would be gained by the process. It must be remembered, however, that in the great majority of practical magnetic-circuits, magnetic material such as iron or steel

TABLE III

| No. | System | $L$<br>cm | $M$<br>gm | $T$<br>sec | $n$ | $p$ | $k$ | $\epsilon_0$ | $\mu_0$ |
|---|---|---|---|---|---|---|---|---|---|
| 1 | Classical C.G.S. electric unrat | 1 | 1 | 1 | $4\pi$ | $4\pi$ | $4\pi$ | 1 | $1/c^2$ |
| 2 | Classical C.G.S. magnetic unrat | 1 | 1 | 1 | $4\pi$ | $4\pi$ | $4\pi$ | $1/c^2$ | 1 |
| 3 | Heaviside-Lorentz rat | 1 | 1 | 1 | 1 | 1 | $1/c$ | 1 | 1 |
| 4 | Maxwell practical Q.E.S. unrat | $10^9$ | $10^{-11}$ | 1 | $4\pi$ | $4\pi$ | $4\pi$ | $1/c^2$ | 1 |
| 5 | Maxwell practical Q.E.S. rat | $10^9$ | $10^{-11}$ | 1 | 1 | 1 | 1 | $1/4\pi c^2$ | $4\pi$ |
| 6 | Giorgi M.K.S. rat | $10^2$ | $10^3$ | 1 | 1 | 1 | 1 | $10^7/4\pi c^2$ | $4\pi/10^7$ |
| 7 | M.K.S. unrat | $10^2$ | $10^3$ | 1 | $4\pi$ | $4\pi$ | $4\pi$ | $10^7/c^2$ | $10^{-7}$ |
| 8 | Dell. Benn. Kar. C.G.S.S. rat | 1 | $10^7$ | 1 | 1 | 1 | 1 | $10^9/4\pi c^2$ | $4\pi/10^9$ |
| 9 | C.G.S.S. unrat | 1 | $10^7$ | 1 | $4\pi$ | $4\pi$ | $4\pi$ | $10^9/c^2$ | $10^{-9}$ |

has to be employed, and that the relative permeability of this material has to be included in the computation, usually through the use of a table or curve sheet. Since the relative permeability factor, has, therefore, ordinarily to be inserted, it is easy to include the $4\pi$ factor in the table or curve sheet, so as to have no necessity for introducing the $4\pi$ term separately. There is thus an economy of time and effort involved in the rationalised process of magnetic-circuit Ohm's law. The Ohm's law formula is, moreover, only one of many in which the $4\pi$ factor appears. In nearly all of them the rationalised formula is distinctly simpler than the unrationalised formula.

A real objection to rationalisation would be the divergence of the practical system from the unrationalised basic C.G.S. magnetic system. The main question to be decided would be whether the very real advantages of rationalisation are counter-balanced by the disadvantage of departure from the corresponding classical C.G.S. formulas.

### QUESTION OF THE UNIT OF LENGTH IN THE PRACTICAL SYSTEM

In addition to, but independent of the question of rationalisation, comes the question of the unit of length to be used. The choice of the length unit logically determines the units of area and volume. It has been shown by various writers, that in order to conform with energy and power requirements, (the *joule* and *watt*), there are only two units within the range of serious consideration; namely, the meter and the centimeter. Theoretically the *quadrant* is also included; but it is so large as to be out of discussion. The quadrant as a unit of length, exceeds the earth's radius. The square quadrant, as a unit of area, is about one-fifth of the surface of the globe, and the cubic quadrant, as a unit of volume, is of the same order as the earth's volume. No one has had the courage to propose these units seriously, and it does not appear that Clark Maxwell, who discovered the relation of the units in this system, regarded them as of a workable character.

The centimeter is a more convenient and familiar unit of length than the meter for most electrical engineering purposes. On the other hand, however, it is linked with a large and awkward unit of mass: $10^7$ grams, or ten metric tons. It is a question, therefore, whether in the general use of the practical system, for purposes other than electromagnetic, the disadvantage of this large mass unit might not outweigh the advantages of the centimeter.

It has been contended that neither the M.K.S. nor the C.G.S.S. system is permissible as a scientific unitary structure, for the reason that in neither of them is unit density the same as that of water. The unit density in the M.K.S. system is the kilogram per cubic meter, which is 1,000 times less than that of water. The unit density in the C.G.S.S. system is 10 tons per cubic centimeter, which is $10^7$ times the density of water. It is of course desirable to have the unit of density identical with that of water, from a practical point of view; but the failure to meet this condition probably is not so serious as some have claimed. For practical purposes, what we need is a table of specific gravities, or the densities of substances divided by the density of water. Once such a table has been prepared, the absolute density of water becomes of relatively small importance. It seems doubtful whether any practical system, otherwise acceptable, should be rejected because its unit of density is not that of any familiar substance.

## Bibliography of Magnetic-Circuit Units

Subsequent to that contained in author's A.I.E.E. paper of January 1931. (*Magnetic-Circuit Units Adopted by the I.E.C.*)

## Discussion

**George A. Campbell:** I should like to call attention to the practical results of the conventions set forth in this paper, as shown by a document which the paper says has used these conventions to the exclusion of all others. I refer to the "Report on Proposed American Standard Definitions of Electrical Terms"[1] sponsored by the A.I.E.E., with Doctor Kennelly as chairman of the committee in charge. It was published last August with a request for comments and suggestions.

Section 35 on "Units and Systems of Measurement" of the Group 05 on "General Terms" defines 5 c.g.s. systems with 27 of the c.g.s. units, next a practical system with 9 practical units, and finally an international system with 10 units. From these definitions the engineer can learn, for example, about the ohm, the abohm, the absolute ohm and the international ohm, but nowhere is he told what ohm is actually used in our shops. The engineer may be impressed with the multiplicity of c.g.s. systems but he cannot fail to find them confusing. Even if he is wise enough to skip the first four-fifths of the text and start in with the international system, he finds that every international unit definition refers him, in the end, to the corresponding absolute unit. This first leads him back to the definitions of the practical units, and then on back to the long, involved definitions of the c.g.s. units and c.g.s. systems.

Would it not be far better, in definitions intended for the electrical engineer, to define first, as briefly and directly as possible, the units which actually are used by the machine shop in the manufacture of electrical equipment, by the retail shop in the sale of electrical equipment, and in the shop talk at all A.I.E.E. conventions? The engineer could then get what he really needs without encountering the artificial difficulties which were invented when the leading scientists hardly had the grasp of electrical units which the youthful radio amateur now seems to have. It would, however, not be feasible to omit all reference to c.g.s. units because the electrical engineer will unfortunately encounter them in the literature of physics. This calls for the familiar conversion table to enable him, upon encountering any c.g.s. unit, to translate it into the shop unit which he really understands.

What I am suggesting is that in this A.I.E.E. glossary of terms relating to units both the order and the emphasis should be inverted. Put the shop ohm, the shop volt, the shop ampere-turn and the shop volt-second first and not the c.g.s. units. There would be no reference to c.g.s. units before the table at the end of the glossary. The shop units would be the basic units and the c.g.s. units would appear as derived units.

If you agree to this, it seems to follow that in his training the engineering student should start at once with the shop units. Then much later he would be introduced to the conversion table for use when, and only when, he encounters a c.g.s. unit in the literature. This plan should work perfectly with boys who have become familiar with the shop electric units as radio amateurs and household electricians. If this is the best procedure with students of engineering, it is, I believe, also the best procedure with high school and college students of physics. It seems quite certain that if a generation of engineers and physicists were trained in this way, they would continue to think and write in terms of shop units, and c.g.s. units would soon become of historical interest only. This, it seems to me, is a goal devoutly to be worked towards, and the present an opportune time for engineers to assist in accelerating the process of education.

Referring again to the A.I.E.E. electrical definitions: under the "International System of Electric and Magnetic Units," on page 34, occurs the statement, "The International Committee of Weights and Measures has decided to discard these units in the near future" in favor, it is implied, of the absolute practical units, as announced in the technical literature. This also calls for inversion, in my opinion.[2] Why? One among several reasons is this: the absolute practical units and all c.g.s. units lead to formulas which are infested with $4\pi$'s and the $4\pi$'s are an unmitigated nuisance in the shop, laboratory and study. The international ohm, ampere-turn, mechanical watt shop system is necessarily free from these $4\pi$'s and such a system is "much simpler to think with and work with," as Doctor Kennelly says. I wish there were time to take up Doctor Kennelly's paper point by point, but in the inverse order of presentation, and show how this inversion simplifies the subject and automatically eliminates one by one the difficulties which he sets forth. I refer especially to: ". . . the difficulties of reaching agreement over the extension of the practical series of units into a complete, comprehensive system," including the meter and ampere-turn, because it requires dropping the density unit and the $4\pi$ of the c.g.s. electromagnetic system; ". . . the ambiguities and confusion which have pervaded international magnetic literature during the last thirty or forty years." ". . . certain ambiguities in the definitions of fundamental electric and magnetic quantities."

To speed the adoption of the shop units as the normal, preferred, universal system, the legalizing acts for metric and electric units, in the United States and other countries, should be consolidated, revised and amplified. That the required changes are small is illustrated by the accompanying table.[3]

---

[1] Report No. 2 of A.I.E.E. Standards.

[2] I cannot see, from the paper under discussion or from other reports of the deliberations of international committees, that the great advantages of relegating the c.g.s. systems to history in favor of a single, preferred system of units, based on the meter, kilogram, second and shop ohm, have adequately been considered by, or even clearly presented to, any of these committees. Many of their votes, therefore seem to me to lack finality.

A DEFINITIVE CHOICE OF MECHANICAL, ELECTRIC, AND MAGNETIC UNITS SUITABLE FOR A LEGALIZED SYSTEM

| Quantity | Unit name (bracketed names to be shortened) | Symbol and defining equation |
|---|---|---|
| 1 length | meter | $L$ |
| 2 area | [square meter] = square meter | $S = L_1L_2$ |
| 3 volume | stere = cubic meter | $V = LS$ |
| 4 time | second | $T$ |
| 5 power | watt | $P$ |
| 6 energy | joule | $W = PT$ |
| 7 force | [joule per meter] | $F = WL^{-1}$ |
| 8 pressure | [joule per meter per square meter] | $p = FS^{-1}$ |
| 9 mass | [kilogram] | $M = Fa^{-1}$ |
| 10 density | [kilogram] per stere | $d = MV^{-1}$ |
| 11 electricity | coulomb* | $Q$ |
| 12 electric current | ampere* | $I = QT^{-1}$ |
| 13 electric potential | volt* | $E = WQ^{-1}$ |
| 14 electric capacity | farad | $C = QE^{-1}$ |
| 15 electric resistance | ohm | $R = EI^{-1}$ |
| 16 electric conductance | mho | $G = IE^{-1}$ |
| 17 electric inductance | henry | $\mathfrak{L} = RT$ |
| 18 magnetomotive force | ampere-turn* | $\mathfrak{F} = NI$ |
| 19 magnetic flux | volt-second* | $\Phi = ET$ |
| 20 reluctance | [ampere-turn per volt-second] | $\mathfrak{R} = \mathfrak{F}\Phi^{-1}$ |

$a$ = acceleration in meters per second per second.

*The five starred units are to be about one-fiftieth of one per cent smaller than the corresponding international units.

The general adoption of these units should make it unnecessary to become familiar with more than one system of units. This would release human effort and soon eliminate the waste and confusion which are a necessary consequence of our present multiplicity of systems. Although the proposed single system of units merely is a selection and a re-alignment of present units, it is not a patchwork expedient. It would sweep away at one stroke all of the major difficulties set forth in Doctor Kennelly's paper.

Doctor Kennelly follows the international committees in considering that the classical c.g.s. magnetic system has been "endorsed, beyond any question of modification, by the Paris Congress of 1900." The literture of physics actually shows, however, that physicists do not consider the c.g.s. electromagnetic system of units suitable for all their needs. Theoretical physicists have substituted the Heaviside-Lorentz systems. Experimental physicists actually make great use of wattmeters, ammeters and voltmeters, together with the farad, ohm and henry. Fundamentally, the choice today is between c.g.s. authority and freedom to use the units which actual experience has shown to be "simpler to think with and work with than those of the classical c.g.s."

**C. L. Dawes:** Professor Kennelly's paper gives a very concise and yet comprehensive presentation of the developments and the present status of the I.E.C. and associated committees in the matter of the standardization of the c.g.s. magnetic units, both in their dimensional relations and in nomenclature. Likewise, the paper states that although practically unanimous agreement has been reached in the retention of eight of the practical units, yet names and even definitions have not as yet been assigned to the other practical units such for example as mmf.

Progress has been made in that definite names have been assigned to the c.g.s. magnetic units of flux, flux density, magnetizing force and magnetomotive force. Moreover, distinction between the controversial units of $B$ and $H$ decisively is indicated in their being assigned the respective names of gauss and oersted. Also the troublesome question of the dimensions of permeability $\mu$ appears to be settled by convention in a very rational manner.

However, so far the c.g.s. unit of reluctance is not named; it would seem highly desirable that a name be assigned to this unit, not only to complete the nomenclature of these related units, but also it is convenient to refer to a unit by name. The name itself is not material so long as it is in general harmony with electrical and magnetic nomenclature. It is the appropriate custom to name the units for savants and the name Weber appears to be the best adapted to this magnetic unit. In the very early days the name Weber was used as the name of the practical unit of quantity and later as the name of the practical unit of current; in more recent years it has been used unofficially in this country as the name of the practical unit of flux, but the names "voltsecond" and "pramaxwell," make the name Weber no longer necessary for the unit of flux. Hence the name Weber appears to be available and could be well recommended as the international unit of reluctance in the c.g.s. system.

It also would seem highly desirable that all the remaining magnetic and electrical units of the practical system be defined and named. This system is the most used by engineers and yet there has been little or no attempt to give names and definitions to the magnetic and electrostatic units (except henry and farad). In this respect I am in substantial agreement with Doctor Campbell.

I believe, however, that the factor $4\pi$ should be retained in the practical unit of mmf. This is in accord with proposition (7) adopted by the S.U.N. committee in Paris in 1932. Although a practical system should lean towards usefulness rather than toward a rational and fundamental derivation, it is questionable if the factor $4\pi$ does produce any more inconvenience when it appears in the numerator than it does when it appears in the denominator either in the physical dimensions of the magnetic circuit or in the permeability of vacuum. The author recommends the ampere-turn as the unit of mmf, stating that in engineering uses of magnetic materials their properties are given as data and curves in which the permeability factor is included, so that the $4\pi$ term in the denominator causes no inconvenience. This same condition has existed for a long time even under present conditions where the c.g.s. unit of mmf having $4\pi$ in the numerator is used. As is well known it has long been customary in scientific work of all kinds to plot the flux density as a function of the ampere-turn per unit length. Hence so far as such data or curves are concerned, it seems immaterial whether $4\pi$ appears in the numerator or in the denominator.

Furthermore all the present units of the practical system have a definite relation to the fundamental c.g.s. system, the unit of length being $10^9$ cm and the unit of mass $10^{-11}$ gram. Elimination of the $4\pi$ factor in the unit of mmf will break this rational relationship between these two systems, which I believe increases confusion and is thus highly undesirable.

With several years' experience, it appears to me that the so-called confusion which the $4\pi$ factor produces, even among students, is exaggerated greatly and is far out of proportion to the efforts being made to eliminate it. The physical picture of a unit charge or unit pole emitting $4\pi$ lines in a medium whose absolute permittivity or whose permeability is unity is simplicity in itself. In fact, to my mind this picture is a much more rational one than attempting to visualize a unit charge or a unit pole emitting only a single line and in a medium whose permeability is $4\pi$. Moreover, the unit charge and the accompanying $4\pi$ lines lend themselves very readily to the very fundamental work and potential relationships which are necessary in the derivations of electrostatic potentials and capacitances.

Only very recently I asked two of my classes one of which was composed of students who had only just begun seriously the study of magnetic and electrostatic units, whether or not the $4\pi$ lines emanating from unit poles or charges, was at all bothersome. They unanimously stated that this convention was very clear to them, in fact was much clearer than the unit line per pole or unit charge. In fact, it has long been our experience that students who are beginning electrostatic and electromagnetic studies have become greatly confused in attempting to use text books where the ampere-turn and the unit line per unit charge conventions are used.

---

[3] This table is taken from the manuscript of a paper under preparation. The same units have been discussed in "Three Superfluous Systems of Electromagnetic Units" *Physics*, Vol. 3, No. 5, November 1932, pp. 230-239, and "A System of 'Definitive Units' Proposed for Universal Use" *Science*, Vol. 61, April 3, 1925, pp. 353-357.

Hence, it is in accord with my experience that the retention of the $4\pi$ term in the practical unit of mmf would simplify the understanding of magnetic relationships rather than confuse them.

I am heartily in sympathy with Doctor Campbell's "definitive" system and the simplicity which it implies, with the possible exception of the unit of mmf just discussed. However, I do not believe that the two fundamental c.g.s. systems should be discarded or even thrust too far into the background, since their units are derived in a simple manner from very fundamental postulates; moreover, even if the "definitive" or an equivalent system were legally adopted, I believe that these two fundamental systems still would be found to be very useful in certain types of scientific work.

**S. L. Gokhale:** The paper divides itself into two parts:

1. A summarized history of the subject up to the present date.
2. Recommendations by the author as to further changes.

The first part contains a table of symbols and units (Table I) suggested by the S.U.N. Committee, and recommended by them for adoption. Doctor Kennelly agrees with the opinions of this committee except on the question of rationalization; that is, Doctor Kennelly stands for omission of the factor $4\pi$ in the equation $\mathfrak{F} = 4\pi NI$, while the S.U.N. Committee has decided to retain it by a vote of 10 to 3.

Table I, column 3, contains what seems to be the defining equations of the concepts in column 1, although they are not specifically called by that name. Construing them as defining equations, we find that their sequence is the reverse of that of the scheme adopted by the I.E.C. and A.S.A. The I.E.C. and A.S.A. first define $m$ the magnetic pole strength. From this they derive $H$ and from $H$, $\mathfrak{F}$ and from $\mathfrak{F}$, $I$. The S.U.N. on the other hand first define $I$ and from this they derive $\mathfrak{F}$, and from $\mathfrak{F}$, $H$. Therefore, the agreement between the I.E.C. and the I.U.P. (International Union of Physics represented by the S.U.N.) as stated by Doctor Kennelly appears to apply to the names of the units and their magnitudes. I hope that it will be possible to work further with a view of arriving at an agreement as to the sequence of the definitions.

With reference to the omission of $4\pi$ in the equation $\mathfrak{F} = 4\pi I$, and its transfer to the equation $B_0 = 4\pi H$, it may be conceded that a large number of scientists favor the omission on the basis of the dimensional conception of permeability, but the point still is unproved.

The practical advantages of omitting $4\pi$ are more apparent than real. For instance, in machine design where the magnetic circuit is partly air and partly iron, the $4\pi$ cannot be eliminated from the computation, for if it is suppressed in the calculation of the iron part of the path, it will reappear in the air part. In only a few instances, such as design of transformers without leakage, can the $4\pi$ effectively be suppressed.

There are other cases in which, though the $4\pi$ does not enter into the numerical computations, has yet to be included in the new form of the equation, and it is possible that it may be forgotten, until the old practices are forgotten and new practices formed. For example, in transmission line calculation, engineers would have to use the formula

$$\frac{2\mu l}{4\pi} \log \frac{d}{r} \quad (\text{where } \mu = 4\pi)$$

in place of the present formula

$$2\mu l \log \frac{d}{r} \quad (\text{where } \mu = 1)$$

without the $4\pi$.

The best policy under the present situation, is a policy of compromise, which permits both parties to hold to their respective views, without interference from the other party. The decision of the I.E.C. in 1930 was the best possible compromise under the circumstances. It permitted one school of thought to assume the physical identity of $B$ and $H$ and to use the equation $B = H$ for space. This equation, though not obligatory to the opposite school, is permissible for them on the hypothesis that $\mu_0$ has been given arbitrarily the value of 1. The compromise also permitted followers of the dimensional conception of permeability to use separate names for the units of $B$ and $H$. Such a policy, though not obligatory to the non-dimensional scheme is quite permissible. This situation might have continued indefinitely without a conflict between the two schools until the question of dimensional character of permeability and the consequent difference in the physical nature of $B$ and $H$ could definitely be settled. An attempt to introduce $4\pi$ into the equation $B_0 = 4\pi H$ at this time would compel the followers of the non-dimensional school to abandon the idea of $B$ and $H$ being physically identical, together with the equation $B = H$. It seems to me that in proposing the change Doctor Kennelly is now going against the spirit of that compromise, which governed the decision of the I.E.C. in 1930. He admits, however, that the change should not be made on the basis of a narrow margin of votes as in the I.E.C. resolution of 1931, (R.M. 97).[4]

With reference to the substitution of the meter for the unit of length in the practical system, while there may be theoretical reasons for advocating this, I feel that in practise it only would add further confusion to the present condition by ending in giving us a third system in addition to the present two.

**Hans Lippelt:** During the discussion of the paper the use of "shop units" in preference to scientific units has been advocated. We do have shop units already, and I think this is a good opportunity to point out that some of them are bad. For illustration I wish to refer to the lb, which is often used in the shop as the unit of the mass. But it is utterly wrong to do so. The unit of the mass is lb-ft$^{-1}$ sec$^2$. If that term is too cumbersome for practical use, then let us find a short name for it and a symbol.

In going over the whole list of shop units, others also will be discovered which cannot bear scrutiny in the light of logic and accuracy. (For instance secondfeet, secft, is used for cubic feet per second.) I think that all such faulty units should be amended to become a true expression of their physical meaning. When short and new names for such units become necessary, exact definitions should accompany them.

Such a purging process should, indeed, be extended also to our technical script. It is customary to write $\sin^{-1}x$* to express an angle $\alpha$ whose sine is $x$, a method which is not compatible with the definition of a negative exponent as given in mathematics. Under this mathematical definition

$$\sin^{-1}x \text{ is equivalent to } \frac{1}{\text{sine } x}$$

and to nothing else.

If internationalism in the language of science and engineering is not objectionable, but striven for, then we might just as well accept the method as used in Europe.

---

[4] Unconfirmed minutes of Meeting Section B on Elec. and Magnetic Units of Comm. No. 1, held in London, Sept. 18, 1931.

*The reader may answer that I have myself used this wrong method of writing. See A.I.E.E. TRANS., Feb. 1926, p. 408, col. 2, last line. My manuscript was correctly written. I had to change these mathematical terms to the customary form, to render my paper acceptable to the committee.

They write arcs in $x$ for an angle (arc), $\alpha$, whose sine is $x$.

$\left.\begin{array}{r} Ar\ \mathrm{Sin}\ y \\ \text{or } \mathbf{Ar\ Sin}\ y \end{array}\right\}$ for the hyperbolic angle (area), $V$ whose hyperbolic sine is $y$.

**W. I. Slichter:** In this paper there are two matters of very great interest to teachers of electrical engineering because they involve the setting up of two new conventions, different from previous practise and because it is the duty of the teacher to prepare the future generations of engineers to accept and use these conventions.

The first is the question of the algebraic sign and the vector representation of reactive power and explicitly: shall inductive reactive power be designated by $+j$ and drawn upward from the horizontal axis in vector diagrams? Either sign or direction may be justified mathematically and scientifically depending upon whether we take current or voltage as our reference vector.

The paper indicates that the international committee prefers a positive sign and upward direction for inductive reactive power, which means taking current as reference vector. This is probably quite satisfactory to those engaged in communication engineering. But those engaged in power engineering are dealing almost entirely with nominally constant potential circuits with one voltage common to all the circuits of the network and they therefore naturally think of voltage as the reference vector. In this case an inductive load means a lagging current and this is so common that we frequently hear the terms "lagging load" and "lagging power factor" where lagging means inductive. Thus these people would naturally prefer the negative sign and the downward vector for inductive power and the converse for anti-inductive or capacitative reactive power. The final choice primarily is one of suiting the habits of the majority of users or that which will involve overcoming the least amount of mental inertia.

The other question involves taking the constant $4\pi$ or $0.4\pi$ out of the magnetomotive force and putting it into the reluctance in the formula for the flux in a magnetic circuit. This again easily is justified scientifically if we ignore the very early development of the art, but more important, this change would put the law for the magnetic circuit in a form similar to that for the electric circuit and the dielectric circuit and make for uniformity and therefore for clarity, logic, and ease of teaching. Moreover, this is done already in most practical applications for every one of our magnetization curves of magnetic steels is plotted between flux density and ampere-turns and not gilberts or $0.4\pi$ ampere-turns. Here the mu and the $0.4\pi$ are made part of the reluctance or reluctivity of the material and the curves give us immediately the ampere-turns which is the quantity of practical interest, and not gilberts. If this change were adopted we would have the three outstanding relations in electrical engineering expressed in a similar manner:

$$\phi = \frac{NI}{R} \qquad R = \frac{1}{0.4\ \pi\mu A}$$

$$I = \frac{E}{R} \qquad R = \frac{\rho l}{A}$$

$$\psi = \frac{E}{R} \qquad R = \frac{1}{KA}$$

**A. C. Seletzky:** Whether or not $+j$ vars or $-j$ vars should be considered as representing inductively reactive power in unspecified alternating current right-angle triangles will probably be decided on the basis of whichever usage predominates in present practise. Both forms may be justified from the viewpoint of mathematical consistency. In view of the fact that $+jx$ has been internationally accepted for some years to represent inductive reactance, inductively reactive power in the form of $I^2(jx)$ would call for a positive sign, current being considered the axis of reference. On the other hand if the voltage were used as the reference axis, inductively reactive power in the form, $E^2(-jb)$, would require a negative sign.

In spite of the fact that capacity loads are encountered in practise, I have observed that engineers generally think subconsciously of reactive power as inductive when it is unspecified, by sheer weight of its more frequent occurrence. Since we generally label quantities, which occur more frequently on one side of an arbitrary line of demarcation as positive, the use of the plus sign to represent inductively reactive power would seem to be the more convenient form. An analogous situation is present in the consideration of positive angles as those which are drawn counter-clockwise from the positive axis of abscissas. Invariably when one is demonstrating anything involving an angle in space, one begins by drawing an angle in the first quadrant counterclockwise from the real axis: it is very probable that this usage grew from manual convenience in drawing angles in this manner and then led to the general acceptance of such angles as positive. It seems that a similar condition obtains in the case of reactive power and that inductively reactive power, from the standpoint of convenience alone, should be considered positive.

**A. E. Kennelly:** Doctor Campbell has well pointed out the advantages of a single system of units over the existing multitude of systems. He advocates extending the present series of nine international practical units (*ohm*, *volt*, *ampere*, etc.) into a complete comprehensive and so-called absolute system, embracing the *meter*, *kilogram* and *second*, with no separate electrostatic system, and with the *ampere-turn* as the official unit of mmf.; *i. e.*, with the system subrationalised. His "Definitive System," substantially the same as the Giorgi system, would be a great boon, if it could be used both in physics and in engineering, to the exclusion of all other systems. In detail, there is some question whether the *international ohm* should be taken at its existing value; or whether it should be first brought more nearly into agreement with the so-called *absolute ohm* of $10^9$ *abohms*; but this is a subsidiary question, outside of immediate discussion.

Professor Dawes points out that there is need for a name to be assigned to the c.g.s. magnetic unit of reluctance, now that the *oersted* has been taken for the unit of $H$. There are many who agree with him. It is to be hoped that a name for the c.g.s. magnetic unit of reluctance may be internationally agreed upon and adopted.

Professor Dawes supports Doctor Campbell's definitive system; except that he wants it left unrationalised, like the existing c.g.s. magnetic system. It was Heaviside and Lorentz who showed the marked advantages of rationalisation; so that a large part of electromagnetic theory is today written in the Heaviside-Lorentz c.g.s. system, instead of in the classical c.g.s. system, owing to the simplification thereby effected. There are thus two sects among basic electromagneticians; namely, the c.g.s. classicists and the c.g.s. rationalists. The question will have to be settled internationally, sooner or later, whether the applied electromagneticians, using practical magnetic units, are to be classicists or rationalists. It is not a question of what is right or wrong; but as to the relative balance of advantages. No classicist should be forced to use rationalised units against his will, and reciprocally. In view of the existing schism in the basic literature, and of the considerable difference of opinion that exists among engineers and technicians in regard to the practical units, it looks at present, as though we might have to recognize the existence of both classical and rational practical units; *i. e.*, both of the *ampere-turn* and of the *ampere-turn*/$4\pi$, and allow both these sub-systems to continue side by side, until international opinion shall have crystallized in favor of one of them; when the other can be formally discharged. This is virtually the state of affairs today in the basic c.g.s. world literature. Not only are opinions on this question of subrationalisation different among electrotechnicians in different countries; but there appear also to be differences of opinion in each of nearly all countries.

Mr. Gokhale points out that we still are unable to decide on scientific grounds, whether space permeability $\mu_o$ has or has not dimensions. We probably will all agree with him on this. There are good authorities on both sides of this vexed question. Ultimately, of course, there can be only one answer. Space permeability $\mu_o$ either is a mere number, or it is not a mere number. The question is of less importance to the engineer than to the physicist; but neither engineers nor physicists can use their symbols, units, or definitions logically, without coming to a conventional agreement upon the question. In the present state of our knowledge of electromagnetism, it probably is better to adopt an international convention, even if it should later be proved wrong, than to carry on indefinitely the confusion of the last thirty years. Thus far, we have had an agreement both in the I.E.C. and in the I.P.U. on the convention that $\mu_o$ has dimensions, and is not a mere numeric.

Mr. Gokhale also properly draws attention to the need of standardizing internationally the definitions of our magnetic quantities. It is very desirable to have this done. The definitions we still cling to are based upon the classical conceptions of magnetic poles, consisting of magnetic point sources. Most physicists admit the validity of these concepts and of the definitions resulting therefrom; but less artificial and more acceptable definitions might be arrived at on the basis of concepts of magnetic flux, obtained from the researches of Ampère, Faraday and Helmholtz.

Professor Slichter has drawn attention to the desirability of having an international convention as to the interpretation of right-angle power triangles when they do not specify the meaning of lagging power. Should lagging power, or $-j$ power, be taken to mean inductively reactive power, or the reverse? Here again is a need for a convention, and not a decision as to right or wrong. He favors lagging power going along with lagging current. General opinion among engineers seems to agree with him. Mr. Seletzky, however, seems to be of the opposite opinion. There probably is no large majority of opinion on this question; but it should be settled as a convention, for general convenience among engineers, and to avoid confusion.

# Empirical Equations for the Magnetization Curve

BY JAMES P. BARTON*

**Associate, A.I.E.E.**

***Synopsis.***—*An empirical equation is derived expressing the permeability in terms of the flux density over an approximate range of 100 to 6,000 gausses. The equation is of the form;* $\mu = P\beta^a$ *and is shown to apply to a variety of magnetic materials including certain alloys. Its greatest range appears to be for silicon content electrical sheet steels. A table is given listing the values of the coefficient and exponent for magnetic materials of various grades. Several curves and tables explain the salient features of the method. An extension of the method of derivation to other parts of the magnetization curve indicates their expression by similar laws or equations. Theoretical considerations lead to an hypothesis of four phases of magnetization coupled by three transitional phases for the entire magnetization curve.*

* * * * *

## INTRODUCTION

THE design of magnetic circuits can be materially assisted by being able to express the relation between electric current and magnetism by means of equations. Numerous attempts have been made during the past century, and for the last 50 years the law formulated by Frolich[9] has been accepted as representing most closely the above mentioned relation. In the course of his study, Gokhale[1] has stated an equation that closely reproduces the measured data for that part of the $\beta$-$H$ curve above maximum permeability and including saturation.

But practically all of the work reported has been in the region between maximum permeability and saturation, leaving that part of the $\beta$-$H$ curve between maximum and initial permeability without a satisfactory expression. It is the purpose of this paper to present a simple equation derived experimentally, covering this part of the curve. As will be shown, the equation holds for commercial electrical sheet steels with silicon content, nickel-iron alloys, electrolyte iron and a cobalt-iron alloy. In the careful examination of the available literature on the subject, no reference has been found covering the procedure reported herein; consequently it is felt that the subject matter may be of value to those interested in magnetics.

*List of Symbols and Nomenclature*

$B$ = flux density, in gausses
$\beta$ = intrinsic flux density, in gausses ($B$-$H$)
$H$ = magnetizing force, in oersteds
$\mu$ = intrinsic permeability ($\beta/H$)
$1/\mu$ = reluctivity

## DERIVATION OF EQUATION AND GENERAL METHOD

In the course of study on simplified methods of design for magnetic circuits, it was observed that the ratio of permeability to the square of the flux density appeared frequently and was of considerable design value. In plotting this ratio *versus* the flux density $\beta$ on log-log paper, it was noticed that apparently a linear relation existed over quite a wide range of flux densities. If this was so, it gave a means for expressing the permeability in terms of the flux density over this straight part.

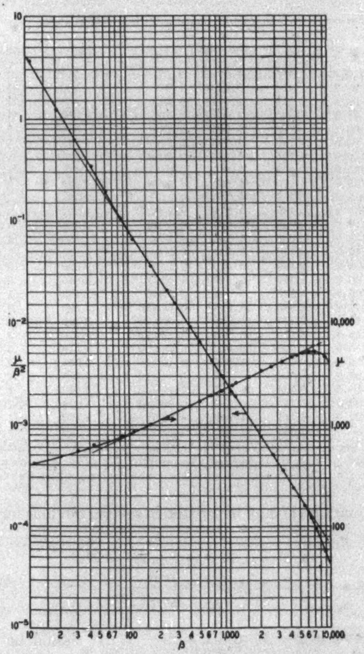

FIG. 1—PLOT OF $\mu/\beta^2$ *versus* $\beta$, AND $\mu$ *versus* $\beta$

For a 4 per cent silicon sheet steel, 29 gage, from data contained in Table I. $\mu/\beta^2 = 93.8\,\beta^{-1.53}$

The derivation is best shown by reference to Fig. 1. The equation for the straight portion is of the standard form $Y = PX^M$ where $P$ is the ordinate intercept of the straight portion extended and $M$ is the slope. From Fig.

*Presented at the Winter Convention of the A.I.E.E., New York, N.Y., January 23-27, 1933.*

1, substituting the equivalent designations for $X$ and $Y$, gives the basic equation

$$\mu/\beta^2 = P\beta^{-M} \tag{1}$$

It will be observed that the flux density is the independent variable and the permeability, the dependent, with $P$ and $M$ being quantities whose values depend upon the nature of the material and are determined by graphical and analytical means from the curve. The values once determined for a given material allow direct calculation of the permeability as a function of the flux density, the equation holding over the straight part of the curve and for that material only. The data for the material are obtained from a sample selected to give the average characteristics.

The per cent deviation gives the difference between the calculated permeability $\mu'$ and the measured permeability $\mu$, by the expression 100 $(\mu - \mu')/\mu$. These data are for a medium grade 4 per cent silicon sheet steel.

Equation (**1**) may be written in several obvious forms, as

$$\mu/\beta^2 = 1/H\beta = 1/\mu H^2 = P\beta^{-M} \tag{1a}$$

$$\mu = P\beta^{a} \tag{1b}$$

$$H = \beta^{c}/P \tag{1c}$$

where: $a = 2 - M$ and $c = M - 1$. It should be observed that the slope of equation (**1a**) is negative while for (**1b**) and (**1c**) it is positive.

The data for Fig. 1 and Table I were obtained on a 4 per cent silicon sheet steel, 29 gage, using the tentative standard of the American Society for Testing Materials, low induction testing method A34-28, section C (1931 bridge method) on a frequency of 60 cycles, with several of the circuit elements changed to allow use of the bridge up to 12,000 gausses. The flux density range covered is from 10 to 10,700 gausses, with the apparent linear portion of the curve between 90 to 5,000 gausses. The equations for the latter flux range, using (**1a**), (**1b**) and (**1c**) with the slope $M$ equal to 1.53 and the intercept $P$ equal to 93.8, are

$$\mu/\beta^2 = 93.8\,\beta^{-1.53} \qquad \mu = 93.8\,\beta^{0.47} \qquad H = 0.01065\,\beta^{0.53}$$

With the equation established for the straight part, it is desirable to see how closely it reproduces the original data. In Table I, the $\beta$ and $\mu$ columns give the original data, with the rest calculated. The permeability $\mu'$ is that calculated by (**1b**). The deviation of the calculated from the measured curve is given by: 100 $(\mu - \mu')/\mu$, in per cent. At the flux densities of 100 and 5,200 gausses, the accuracy of reproduction is plus or minus 3 per cent, while between these limits the numerical value is considerably less, amounting to about the value of the accumulated errors.

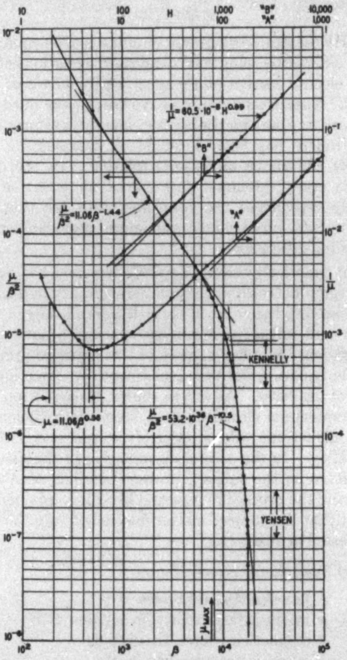

FIG. 2—PLOT OF $\mu/\beta^2$ *versus* $\beta$, AND $1/\mu$ *versus* $H$

For a poor grade of 4 per cent silicon sheet steel, from data contained in Gokhale's[1] paper (Table I and Fig. 1)

In Fig. 1, the $\beta - \mu$ curve is shown in relation to the $\beta - \mu/\beta^2$ curve. It will be observed that the apparent range of the straight part is much greater for the $\mu/\beta^2$ curve than for the $\mu$ curve. By analytical geometry the ratio of the ordinates and the ratio of the lengths of

Samples 1, 2 and 3 were measured in laboratory.

Sample 4 data from Armco curve No. 2040, from Bulletin "Armco Electric Sheets for Radio Applications."

Samples 7, 8 and 9 from Follansbee standard published sheets, R-1002-E, R-6002-E, and R-7002-E, respectively.

Samples 5, 6, 11, 12 and 13 from Tables IV, I, IX, VI and X, respectively, S. L. Gokhale's *Law of Magnetization*, TRANS. A.I.E.E.

The permeability $\mu''$ is that for the lowest value of flux density given in the column "range covered." The last two columns give the maximum value of permeability and the flux density at which it occurs.

the curves can be obtained from the slopes, for the same range of abscissa. For this sample, Fig. 1, and the same flux range, the $\mu/\beta^2$ ordinate is 3.29 times the $\mu$ ordinate. Likewise, the length of the $\mu/\beta^2$ curve is 1.66 times that for the $\mu$ curve. Being able to spread out the magnetization curve by use of $\mu/\beta^2$, tends to increase the accuracy in drawing the mean curve. Thus it may be said that the coefficient and the exponent for the equation are obtained by expansion of the curve; then by simplification of the equation a contraction of the curve results when plotted to the same abscissa scale. It should be observed that multiplying equation (**1**) by $\beta^2$ changes the slope from negative to positive, giving equation (**1b**).

Besides showing that this equation held over the flux range in question for measurements made in the laboratory, a considerable amount of published data was carefully examined, part of it being listed in Table II. Some of the data fell slightly short, either in the high or the low flux densities of fully covering the part of the magnetization curve being investigated. In all cases, however, the straight part existed. In most cases the deviation in reproduction was less than plus or minus 1 per cent over a wide range of flux densities. This equation appears to hold equally well for data taken by direct or alternating current methods.

Continuing with Table II, it will be noted that the coefficient $P$ covers quite a wide range of values, while the exponent $M$ does not vary so greatly. If it is considered that initial permeability exists at a flux density of one gauss, then the coefficient $P$ becomes the calculated permeability. See equation (**1b**). As the true $\beta - \mu$ curve approaches $\beta = 0$, it becomes tangent to the ordinate value corresponding to initial permeability, whereas the calculated curve is straight and intercepts this ordinate at an angle, when plotted on log-log paper. Thus the calculated permeability is less than the true permeability, for $\beta = 1$ gauss, and $P$ can undoubtedly be used to rate a sample of steel as to the relative magnitude of its initial permeability. Just how far this idea can be carried will have to be determined for a large number of samples.

The data in Table II for $P$ show an application of this idea, and can be seen for samples 1, 2 and 4 at ten gausses, and samples 7 and 9 for twenty gausses. Also, the two samples 5 and 6, which are poor grades of steel, have low values for $P$, the permeability being very low even at 500 gausses. Again, referring to samples 10 and 11 for nickel-iron alloys, 10 is particularly good with a permeability of 3,050 at 3 gausses, whereas sample 11 has a permeability of only 1,220 at 170 gausses. These values of $P$ for 10 and 11 are in keeping with the above mentioned idea and show how superior sample 10 is to 11 as a high initial permeability material. It is desirable to point out that the data on the various materials of Table II were selected from among many published and laboratory measurements to show that the method was general, holding for good and poor grades of silicon sheet steel and various alloys.

Just what function the exponent $M$ may infer as to the nature of the material, or a clue to its properties, is not clear at this time.

## EXTENSION OF METHOD TO OTHER PARTS OF THE MAGNETIZATION CURVE

It is of interest to compare the $\mu/\beta^2$ *versus* $\beta$ graph of a magnetization curve with that of the $1/\mu$ *versus* $H$ graph, which is an expression of Frolich's equation. See Fig. 2. The data selected are from Gokhale's paper[1] (Table I, Fig. 1). As the material is a very poor sample of sheet steel, the straight part is rather short and lies between 900 and 5,000 gausses, giving the equation: $\mu/\beta = 11.06\beta^{-1.44}$. The low valued coefficient indicates the very low initial permeability.

Continuing with Fig. 2, there appears a second straight part, between maximum permeability and saturation, which lies between that region investigated by Kennelly and that by Yensen. The equation for this sector involves very large numerical values for the coefficient and exponent, as is evidenced by the nearly vertical slope. The third straight sector is vertical and is that part for which ($\beta$) is constant, *i. e.*, saturation. These two sectors and the connecting part are ably covered by Gokhale's[1] equation (**30-2**): $\beta = S(1 - be^{-aH})$. The equation for the second sector involving the large valued coefficient and exponent, reproduces the curve very closely.

The only apparent straight part of the reluctivity curve, Fig. 2, is in the vicinity of and including saturation, and can be expressed by the equation: $1/\mu = 60.5$ $H^{0.99}\ 10^{-6}$. Comparing the accuracy of reproduction using this equation *versus* the reproduction data calculated by Gokhale's[1] (Table I-III), indicates that the former gives about half the accuracy of the latter, both operating over the same range. Noted on the reluctivity curve, Fig. 2, is that part reported in this paper, $\mu = 11.06\,\beta^{0.56}$.

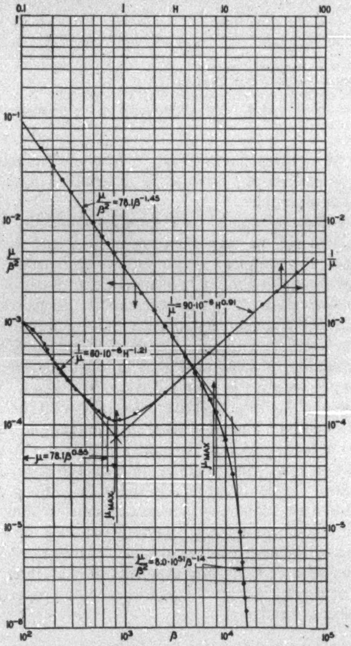

FIG. 3—PLOT OF $\mu/\beta^2$ *versus* $\beta$, AND $1/\mu$ *versus* $H$

For a good grade of 4 per cent silicon sheet steel, from data contained in Table III

The reluctivity curve has been shown by Gokhale[1] to be quite insensitive to variations in magnetic characteristics, and it only appears as a straight line when saturation is approached. Many text books, when showing the magnetization curves, use co-ordinate paper with scales so arranged as to crowd the low induction region, seemingly to indicate that the only region of interest is above maximum permeability to saturation, whereas all portions of the $\beta - H$ curve are equally important. It is this latter range that appears as a straight line when plotted to the same scale to illustrate Frolich's law and which is misleading in appearing to cover the entire $\beta - H$ curve. The use of log-log or semi-log paper for expressing the magnetic relations has been more private than public. It is urged that wherever expedient, the log-log and semi-log papers be used, especially in text books so that the magnetization curve may be revealed as completely as possible, without favoring any one section.

In Fig. 3 are shown curves for a 4 per cent silicon sheet steel of good quality, in the flux range of 100 to 16,000 gausses. The equations of $\mu/\beta^2$ *versus* $\beta$ for the two straight parts on either side of maximum permeability are given. For the reluctivity curve, it appears that the region above maximum permeability, for this material, can be expressed by an equation of the same form as discussed for Fig. 2, with the range considerably increased. It is interesting to note that the reluctivity curve is not as straight below maximum permeability as it is above. By drawing in the average straight line, it was found to intersect the extended straight line from the other straight part, at maximum permeability. This has been observed for several other samples and may be of some interest, or value. The degree of reproduction for the lower part of the reluctivity curve is very poor compared with that for the upper part using the equations noted on the curve in Fig. 3. Of greater interest is the fact that the permeability below maximum can be much more closely stated by $\mu = 78.1\,\beta^{0.55}$, as derived by the method of this paper, than by $\mu = 16{,}660\,H^{1.21}$, as derived from the reluctivity curve. This can be seen by referring to Table III which gives the deviation in per cent for the two equations.

## THEORETICAL CONSIDERATIONS

From the examination of considerable data such as reported in Table II and elsewhere, it appears that the entire magnetization curve when plotted $\mu/\beta^2$ *versus* $\beta$ on log-log paper, can be said to consist of four straight sections joined by three curved sections. Starting with saturation, $\beta$ is constant and $\mu$ continues to rise slowly in value from in the vicinity of unity. The curve is vertical, with the coefficient and exponent infinite in value. The second straight section, between saturation and maximum permeability, yields very large values for the coefficient and exponent. The third straight section, between maximum and approaching initial permeability (the section reported on in this paper) has comparatively low values and covers a large range of flux densities. The fourth section is that which terminates in initial permeability, where $\mu$ approaches a

The permeability $\mu'$ is that calculated by $\mu' = 78.1\,\beta^{0.55}$; $\mu''$ is that calculated by $\mu'' = 16{,}660\,H^{1.21}$. The per cent deviation shown by the last two columns indicates the difference between the measured permeability $\mu$ and the calculated permeabilities $\mu'$ and $\mu''$ by the relation $100\,(\mu - \mu')/\mu$ per cent. The first two columns, $\beta$ and $\mu$, give the data measured on a good grade of 4 per cent silicon sheet steel.

constant value as $\beta$ approaches zero. For this fourth section, the limiting value of the slope exponent is 2, and the coefficient value becomes very nearly equal to the initial permeability. Table IV lists average values for the coefficient and exponent of the four sections, for good grades of 4 per cent silicon sheet steel.

Considering the three curved sections, it has been observed and shown in Fig. 2 that in general the radius of curvature is less for the curved section containing maximum permeability than for the curved sections on either side. In several sets of data there was a slight indication of a short flat $S$ shaped section in place of the curved section terminating in saturation.

As the $\mu/\beta^2$ ordinate also represents $1/\beta H$ and $1/\mu H^2$ (see (**1a**)), the flux density is also a function of the magnetizing force $H$. From the general shape of the whole curve, there appears to be four distinct phases of magnetization obeying definite laws of the same form, which are represented by the straight sections of the curve when shown on log-log paper. Also, there are three transitional phases as represented by the curved sections, for which expressions have not been derived. Although these four phases of magnetization can be observed in a general way from the usual $\beta - H$ curve, it is not obvious they follow apparently similar laws.

Starting with very low values of $H$, it can be conceived that a small number of loosely bound magnetic units exist that can be oriented in the same direction by weak magnetizing forces, following a definite law. As $H$ increases, passing the first curved section, a range of values is reached which is capable of orienting the majority of the units. This is the range reported by this paper. There still exist a goodly percentage of the units more closely bound and it requires much greater values of $H$ to orient these with the others. This gives the straight section preceding saturation. Lastly, all have been oriented and saturation exists, this straight section extending onward with increased values of $H$ and decreased values of $\mu$. For some materials there may exist the small secondary transition section terminating in saturation, as mentioned above.

TABLE IV—AVERAGE VALUE OF COEFFICIENT AND EXPONENT FOR THE FOUR SECTIONS OF THE MAGNETIZATION CURVE FOR 4 PER CENT SILICON SHEET STEEL

| Section of curve | $P$ | $M$ | Equation |
|---|---|---|---|
| 1. Saturation | $\infty$ | $-\infty$ | $\mu/\beta^2 = \infty/\beta^{\infty}$ |
| 2. Between saturation and maximum permeability | $1 \cdot 10^{51}$ | −14 | $\mu/\beta^2 = 1 \cdot 10^{51}/\beta^{14}$ |
| 3. Between maximum permeability and approaching initial permeability | 80 | −1.5 | $\mu/\beta^2 = 80/\beta^{1.5}$ |
| 4. Vicinity of and including initial permeability | 375 | −2.0 | $\mu/\beta^2 = 375/\beta^2$ |

Note: For section No. 4, $M$ has a limiting value of two; the actual value may be slightly less than two.

Experimentally to prove this hypothesis concerning the definite steps in complete magnetization of a material, it will be necessary to examine carefully a large number of samples over the entire range of the magnetization curve. The available data have indicated that this process apparently exists, at least within the limits of accuracy of plus or minus 1 per cent; consequently the author presents these findings for further consideration.

### CONCLUSIONS

In conclusion, the following summary may be stated:

1. An equation of the form: $\mu = P\,\beta$ has been derived experimentally which closely reproduces the flux density-permeability curve for magnetic materials of various compositions and quality, in the flux range of approximately 80 to 6,500 gausses.

2. The coefficient $P$ and exponent $a$ are determined from the data by graphical and analytical means, both being influenced by the nature of the material, with the former being indicative of the relative value of the initial permeability.

3. An extension of the method to other portions of the magnetization curve, indicate three other regions which can be expressed by similar equations.

4. Theoretical considerations of the entire magnetization curve as given by $\mu/\beta^2$ *versus* $\beta$ on log-log paper, indicate that there are four distinct phases of magnetization coupled by three transitional phases. Each of the four phases may be given by the general equation: $\mu = P\,\beta^a$, with $P$ and $a$ having different values.

5. The degree of accuracy in obtaining these empirical equations is sufficient for most commercial design purposes to allow their use in calculation over the flux densities for which they hold, without reference to the $\beta - H$ curve.

6. The data plotted as $\mu/\beta^2$ *versus* $\beta$ for the entire range of the magnetization curve are useful for certain design procedures where it is desirable to obtain $\beta$ for various values of $\mu/\beta^2$, which frequently appears in certain methods of design.

### ACKNOWLEDGMENT

The author wishes to express his appreciation to Professor J. H. Kuhlmann of the University of Minnesota, for a preliminary reading of the paper; to Mr. R. L. Sanford, of the Bureau of Standards, for certain comments on the method involved; to Mr. S. L. Gokhale, for the use of data from his paper[1]; to the American Rolling Mills Company and the Follansbee Brothers Company, for permission to use data from several of their published curves; and to Mr. N. S. Neilson, for his kind assistance in operating the laboratory equipment and taking data on numerous samples of sheet steel.

## Appendix

The general equation $Y = PX^M$ can be expressed in logarithmic form as

$$\log Y = \log P + M \log X \qquad (2)$$

Equation (2) is of the form $Y = P + MX$ which is the equation of a straight line when plotted on coordinate paper. The coefficient $M$ in (2) or exponent $M$ in (1) is obtained on either the coordinate or log-log papers, respectively, by linear measurements, as $M$ is the slope of the straight line. The intercept $P$ is obtained by extension of the straight line to intersection of the ordinate for $X = 1$.

Generally, the slope $M$ can be more accurately measured than the intersection of the ordinate $P$ by extension of the line graphically. By the several methods available for drawing in the mean straight line through the data points, the slope can be determined by measurements or by calculations. Then by using values for $X$ and $Y$ taken from the curve or data, the value of $P$ can be calculated. This procedure is sufficiently accurate for most design purposes. The equivalent designations for $X$ and $Y$, for the specific case at hand, are $\beta$ and $\mu/\beta^2$, respectively, and the equations can now be thrown into any form desired.

## Discussion

**G. H. Cole:** The Barton method of extrapolating data to a very low induction should be very useful in correlating a-c and d-c tests on materials intended for radio applications. Most d-c permeameter methods suitable for accurate determinations of permeability at high induction are not sufficiently sensitive for low induction work. On the other hand, a-c methods of permeability measurement are usually inaccurate at moderate and high inductions, due to the difficulty in determining the peak value of the a-c wave. By means of the Barton equation, these can now be correlated. Evidently, no appreciable difference exists between the two types of tests judging by the checks which are reported in the paper.

Our experience indicates that the permeability at inductions of 100 gausses or less is the best criterion of quality of electrical sheet steel used in certain radio receiver applications, such as audio transformers. The methods given in the paper for extrapolating magnetization data into this range should be convenient and helpful. For the above-mentioned application our experience has been that it is not necessary to determine the permeability for inductions of less than 1 gauss, and hence determinations of $P$ in equation (**1b**) can be used as the initial permeability.

**S. L. Gokhale:** About 5 years ago, that is, shortly after the publication of my *Law of Magnetization*, (A.I.E.E. Trans., Vol. XLV, June 1926, p. 1013) our laboratory started to extend our study to the lower part of the magnetization curve. We found the Baur's Law ($\mu = aH + b$), which had already received confirmation from Raleigh, approximately but not strictly correct. We tried also an equation of the form $\beta = aH^b$, and did not have much success. Mr. Barton's paper is, therefore, a great surprise to me, because his equations $\mu/\beta^2 = P\beta^{-m}$ and $H = \beta^c/P$, merely are two other forms of the equation $\beta = aH^b$ which did not appeal to me as very promising. Mr. Barton's success with the same equation suggests among other possibilities the possibility that I might have overlooked something.

Mr. Barton has used an imperfect magnetic circuit with strips; with proper precautions to minimize the effect of this imperfection, and has also used a 60-cycle alternating current. We had used toroid rings and direct current, and it seemed at first that this difference in the methods made the difference in the result. But Mr. Barton has successfully extended his equation to our data, which makes it necessary to look for an explanation somewhere else.

As to the several phases in the progress of the magnetization curve, this same conclusion had been reached by the Bureau of Standards (Scientific Paper No. 404, p. 741).

**Hans Lippelt:** This paper embodies a study of magnetization curves and their evaluation in search of a mathematical term which would relate the magnetizing current to the magnetic flux. As a solution a simple formula $\mu = P\beta^{\alpha}$ is offered as the result of reported experiments with alternating current.

The author also follows precedent when defining $\mu = \dfrac{\beta}{H}$ not $\dfrac{B}{H}$.

As stated in the paper, the relation is empirical, and I wish to go a step further by saying that the quantity $\mu$ in itself is an empirical quantity. This applies notwithstanding the fact, that we have assigned to $\mu$ the good and descriptive name permeability, which, it is conceded, defines $\mu$ as a property of the material. (See explanation given in the paper after quoting formula (**1**).)

It is my contention that this property of the material is not retained in its virgin state as the progress of magnetization goes on. It is interfered with by physical reactions such as set up by hysteresis, temperature and mechanical stress.

The erratic character of $\mu$ will readily be recognized by an inspection of Table IV, which discloses that the "constants" $P$ and $\alpha$ of the fundamental formula vary very greatly over the full range of magnetization.

It seems after all that a quantity

$\nu = \dfrac{\beta}{R}$ where $R$ ($- R$ to be correct) represents that part of $H$, which is available for magnetization proper has more justifition, than $\mu = \dfrac{\beta}{H}$ or $\dfrac{B}{H}$. Compare herewith A.I.E.E. Trans., February 1926, p. 395 under paragraph 2*b*; and also p. 396, equation (2).

The author of the paper refers repeatedly to Mr. Gokhale's paper on the *Law of Magnetization*. The latter is given as

$$\beta = S\,(1 - be^{-\alpha H})$$

and is said to apply for the region near saturation. Mr. Barton states further that Gokhale's equation very closely reproduces the curve of $\dfrac{\mu}{\beta^2}$ as shown in Fig. 2 of his paper, but he does not undertake to prove that

$$\frac{\mu}{\beta^2} = \frac{1}{H\beta} = PB^{-M} \text{ is equivalent to } \frac{1}{HS-(1be^{-aH})}$$

as proposed

a sequence to Gokhale's equation

$$\text{or } \frac{1}{P}\,\beta^{M} \text{ equivalent to } HS\,(1 - be^{-aH})$$

a proof which would greatly enhance the author's work.

While explaining Fig. 2 of his paper, the author speaks of the "second straight part," situated between Kennelly's and Yensen's range. He also asserts that this second straight part (and the third) is well covered by Gokhale's equation. But just for this "second part" Gokhale admits that Frolich's Law applies. (See A.I.E.E. Trans., June 1926, p. 1023, section 19, paragraphs 8 and 7, *a* and *b*.) It does not seem plausible that the law of magnetization should change in the short interval *between* the two regions cited. In the introduction to the paper it is claimed that Frolich's Law is not reliable. A conclusive statement should be presented.

Referring now to Fig. 3 of the paper and corresponding text: if the author asks for an answer as to why the "two straight lines" of the reluctivity curve intersect for $\mu = \mu_{max}$, he will probably find it by:

1. Observing what the writer set forth in his own paper on the *Magnetic Hysteresis Curve*, A.I.E.E. Trans., 1926, p. 406, Chapter VII in connection with Fig. 14.
2. Observing, as stated at the beginning of this discussion, that $\mu$ is an erratic quantity and should be replaced by $\nu = \dfrac{\beta}{R}$.
3. That when taking note of hysteresis

$$\mu = \infty \text{ when } H = 0, \text{ namely } \mu = \frac{\text{Remanent magnetism}}{H \text{ (which is zero)}}$$

$$\mu = 0 \text{ when } H = \text{coercive force } \mu = \frac{\text{Zero magnetization}}{\text{Coercive force}}$$

and that this coercive force depends on the highest value of $\beta$ obtained under the a-c cycle.

4. That by using alternating current, these important characteristics, remanent magnetism and coercive force, are removed from observation and cannot provide premises for a conclusion such as is sought.

That an exponent (like $\alpha$) may be attached to magnetic quantities (as $\beta$ for instance), when the law of magnetization is finally established, is indicated also in the discussion printed in the A.I.E.E. Trans., 1926, p. 412, equation (e).

In order to unveil the law of magnetization, as it applies between positive and negative saturation, the *complete physical state* of the material (and its changes during the process) should be taken into consideration, to wit: molecular friction (hysteresis), temperature and mechanical stress.

Ewing has written a book on the influence these physical states have upon the process of magnetization (see the references to this on page 413 of the aforestated reference). When truly observed they will illuminate the author's conclusion No. 4.

**A. C. Seletzky:** Over the range of introduction studied, Mr. Barton has discovered an empirical relationship, which for practical purposes connects the values of induction and magnetomotive force with a reasonable degree of accuracy. The value of the expression as experimentally determined, $\mu = PB^{\alpha}$, is however seriously undermined when considered theoretically because both sides of the formula do not have the same dimensions. Although the dimensions of $\mu$ itself are not known, its role as a factor in the expression $[k\mu]^{-1/2} = v$ is well established; ($k$ = dielectric constant, $v$ = velocity of light). Hence whatever the dimensions of $\mu$ might be, they must remain constant for all magnetic materials, if the dimensions of the dielectric constant remain fixed. The expression of Mr. Barton, $\mu = PB^{\alpha}$, admitting a variable exponent gives a different dimension for $\mu$ with every distinct value of $\alpha$ since $P$ is a numerical constant. From Table II in the paper, this exponent under the column heading $(2 - M)$ varies from 0.290 to 0.758.

The expression obtained by Gokhale, $B = S\,(1 - be^{-aH})$, although open to a number of weighty objections based both on theoretical and experimental evidence, as has been pointed out by Sanford,[1] does at least have the same dimensions on both sides of the equality sign. Hence in time, it may be modified without changing its form. I do not wish to detract in any way from the practical significance of Mr. Barton's findings, but merely to point out that if any considerable headway is to be made into the determination of the functional relationship existing among magnetic quantities, that it is necessary to start with expressions which at least satisfy the law of dimensions. Thus, I venture to propose that Mr. Barton make an attempt to throw his expression into another form which will satisfy this condition; before this is done it is useless to read any physical significance into any of the constants of the formula as it now stands.

**A. C. Schwager and V. A. Treat:** The general use of log-log paper is advocated for the analysis of magnetization curves and the advantages gained thereby are pointed out. The author is to be complimented for bringing these facts to the general attention, if they are utilized they will result in great advantage wherever they can be applied.

This will be shown for one specific case, the current transformer. It is well known that current transformers operate in the range of low flux density. The usual method is to plot on log-log paper, the reactive voltamperes per pound of the core material in relation to the flux density. T. D. Yensen has shown such a relation for silicon iron and nickel iron (permeability of hypernik reaches 167,000, *Electrical World*, June 1931). From Fig. 6, it is seen that the rva per lb, over a wide range are approximated by a straight line, resulting in rva per lb = $B^{1.6}$. The expression for magnetizing current then immediately follows:

$i_m = cB^{0.6}$ and the permeability $u = d\dfrac{B}{i_m} = eB^{0.4}$, the last relation having been illustrated on log-log paper by Keinath, *ETZ*, 1932, p. 1596. We have made use of this relation to express analytically the performance of current transformers over their normal operating range.[2,3] In this manner the variation of the phase angle with the secondary current of a specific transformer with a secondary burden $r$ and $N$ secondary turns can be represented by:

$$\theta = \text{const.}\,\frac{r^{0.4}}{N^{1.6}\,I_2^{0.4}}\ \text{minutes.}$$

The usual time consuming method of calculating transformer characteristics point by point thereby is eliminated. The application of Frolich's Law, or of the formula given by the author for high flux density, furnishes formulas for the overload characteristics.

The advantages which result from this procedure in the case of current transformers, apply to any other magnetic circuit, and it is hoped that Mr. Barton's paper will further point out the benefits of such a method.

**James P. Barton:** The writer has not had the opportunity to demonstrate Mr. Cole's suggestion, but as equation (1) reproduces satisfactorily the intermediate range of the normal magnetization curve from data taken by the d-c ring permeameter and the a-c strip bridge methods, it is felt that measurements on the same sample by the two methods, properly conducted, should be joined by equation (1). If reasonable assurance is to be had that the magnetic circuit conditions are equivalent to each other for the two standard methods, then the values for the coefficient and exponent should very closely agree. The sample should be thoroughly demagnetized before each run, and probably for best results the values of $H$ should be increased from minimum to maximum.

Mr. Gokhale's reference to the *Bureau of Standards Scientific Paper No. 404*, on the several phases in the progress of magnetization, discloses a general and obvious division of the curve into three parts, the divisions occurring in the foot and knee sections of the magnetization curve but not in a well defined manner. The procedure given in this paper under discussion allows a definite division of the curve into the several phases, as they are expressed by equations whose graphs intersect, forming definite divisional points.

It is surprising to learn that others have considered equations of similar form for the same range covered as disclosed in this paper, but not surprising to note that Mr. Gokhale's laboratory did not arrive at satisfactory results upon consideration of this method. The writer is greatly interested in this and would be glad to learn of any conclusions as to where the difference lay.

It is possible that precise measurements may disclose greater deviations than shown, although the curves drawn to published data taken under presumably carefully controlled conditions yield no greater deviations from the calculated curve than for what we may term commercial grade measurements. Because of the apparently consistent performance of the method when tried with data obtained by various methods and degrees of accuracy, it was felt to be possibly of more value than just for design purposes. Thus the urge for the procedure to be investigated further.

Mr. Lippelt's comments on permeability express the writer's feelings in that when it is said a sample has a certain permeability, we must go further than that single statement, if that value is to be of use to us. The value of $\mu$ depends so much on the history of the sample as well as its physical state at the time of measurement, that it is felt many sins are committed in its name. In connection with the effect of hysteresis, the writer did not have any satisfactory data at hand for testing equation (1) on the branches of the loop.

Referring to Fig. 2 of the paper, Gokhale's equation is of such a form that it covers the range preceding and including saturation with a smooth curve, whereas when expressing the curve as $\beta$ *versus* $\mu/\beta^2$, this same region appears as two straight lines joined by a curved section. In reproduction of the data by both equations, there is close agreement over the common portion, but I do not know which one, including Frolich's, more nearly expresses the true law of magnetization.

All of the attempts at the law of magnetization undoubtedly are building stones for the structure that eventually will house that law. The work entailed in determining the limits of application and the testing of these attempts is truly tremendous, because of the great variety of materials to be covered as well as the variable physical and chemical states of these materials. This is emphasized by the fact that many have limited themselves to certain portions of the curve for a continued study, which for most of the equations has been in the neighborhood of saturation.

This paper was presented only after it was reasonably well shown that equation (1) held over the intermediate range of the normal magnetization curve, when commercial and laboratory data were used as measured on various materials in random physical states. The theoretical discussion briefly was limited only to what appears to be the first division of the normal magnetization curve into segments each expressed by equations of the same form, providing natural divisional points at the intersection of their graphs.

# The Dielectric Losses in Impregnated Paper

BY J. B. WHITEHEAD*
Fellow, A.I.E.E.

***Synopsis.**—Accurate measurements have been made of the electrical and other physical properties of 10 insulating oils, of a single grade of wood pulp paper, and of the paper when impregnated with each of the oils. Short time charge and discharge curves under continuous potential have thrown further light on the anomalous conduction as found in oils, and permit the separation of the total dielectric loss into two components.*

*Of the total increase of the loss found in impregnated paper, over the separate losses in oil and in dry paper, one component is proportional to the effective conductivity of the oil. The other component, due to reversible absorption, is, for a given paper, a definite function of the free ion content of the oil as indicated by the product of the conductivity by the viscosity. These relations hold over the entire ranges of type of oil and temperature under study.*

*The product of conductivity by viscosity is proposed as a measure of the "electrical purity" of an oil used for impregnation.*

*The simplicity of the relations shown suggests that an extension of these studies to other grades of paper should make it possible to predict accurately, from the separate properties of paper and oil, the electrical behavior of any grade as impregnated with any type of oil.*

* * * * *

## INTRODUCTION

By the sufficient refinement of the oil and the paper, and by careful elimination of air and moisture, the dielectric losses in impregnated paper may be reduced to very low values. Thus, at ordinary temperatures, values of the power factor of the dielectric in high-voltage cables and in impregnated paper condensers may be had within the range 0.001 to 0.003. This means that under most conditions the losses in the dielectric in high-voltage cables are relatively small as compared with those in the conductor, and so do not seriously limit the current carrying capacity of the cable as related to the rise of temperature of the insulation.

On the other hand, the dielectric losses in cables commonly increase in service, and the relation of these changes to the stability of the insulation and the life of the cable is one of the most important problems confronting the manufacturer and user of cables of this type. Little is known as to the relation between the dielectric loss of impregnated paper and the separate losses in the constituent oil and paper. It is generally known that the lower the conductivity and power factor of the oil, the lower the resulting loss in the impregnated paper, and it is also known that the loss in the impregnated paper is generally substantially greater than the joint losses in oil and paper separately. Quantitative relationships, however, have never been established, largely due to the fact that until recently, the possible measurements have been limited to those of alternating loss and power factor, and of conductivity under continuous potential. Owing to the complexity of the materials and the number of factors entering, satisfactory correlation and prediction of final losses have not heretofore been possible. The predetermination of the electrical behavior of a complex dielectric, in terms of the behavior of its constituents is one of the most obscure problems in the whole field of dielectric behavior. The reason for this is found in the fact that no single insulating material, however carefully refined and prepared, possesses the characteristics of an ideal dielectric, which should show only specific inductive capacity. We have in Maxwell's theory a very satisfactory explanation of the a-c behavior of complex dielectrics of which the constituents possess only inductive capacity and conductivity. However, few if any available insulating materials satisfy even these simple conditions. As a consequence, while many complex dielectrics approach the behavior predicted by theory, in general the agreement is roughly qualitative only. In particular, in the case of insulating oils and cellulose paper, each of these materials is so complex in its dielectric properties that, to the experimenter, it is almost immediately obvious that a quantitative agreement with any theory of dielectric loss cannot be expected from the studies of the behavior of the paper when impregnated with the oil.

*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

Nevertheless, although a convincing theory and experimental agreement therewith may not be expected, it is yet entirely possible to study more closely and with careful quantitative measurements, the behavior of these substances separately and in combination, and to examine the results to see if any correlation is possible between the original general physical properties of the constituent materials and the dielectric losses of their combination. In this paper we are reporting some studies of this character. The general plan has been to adhere as closely as possible to one type of paper, to vary the oil over as wide a range of types as possible, to study the electrical and other physical properties of each, and the electrical properties of their combination, over the range of temperature 25 deg to 65 deg, this being the important range of cable operation.

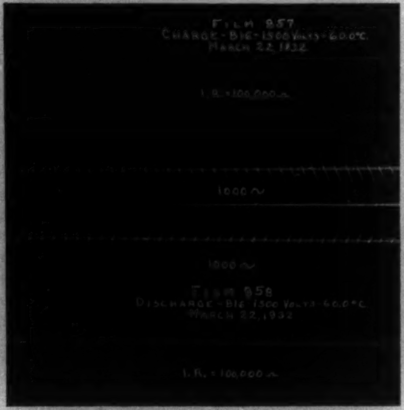

Fig. 2

## Experimental Method

The test specimens were in the form of cylindrical capacitors. The central high-voltage electrode was a brass tube 5.8 cm outside diameter, 61 cm long, on which 0.1 mm thick wood pulp paper was spiralled as in impregnated paper cables, with butt joints between tapes, and to a depth of 15 layers. The outer electrode was of sheet lead and provided with guard electrodes. For the oil a second capacitor of approximately equal dimensions was used. Each capacitor was mounted in a separate constant temperature vacuum tank. The oil was thoroughly degassed by spraying into a vacuum, and the paper thoroughly dried by heating under vacuum. After the measurements on the oil were made, the oil was drawn under vacuum into the tank containing the paper capacitor, impregnating the latter without intervening exposure to air.

Electrical measurements were made under both alternating and continuous voltage. Dielectric loss, power factor and capacitance, as related to temperature between 25 deg and 65 deg C, were measured at 60 cycles over the range 500 to 1500 volts effective values, on a high sensitivity Schering bridge. The measurements under continuous voltage were the short and long time values of charge and discharge currents and the irreversible absorption, initial and final conduction, as deducible therefrom. Charge and discharge currents beginning one millisecond after the application of voltage or of short circuit were read, using the amplifier oscillograph. This instrument increases the normal sensitivity of the electromagnetic oscillograph $10^5$ times giving a deflection on the photographic film of 1 mm per $4 \times 10^{-8}$ amp.

The short time charge and discharge curves, as read on the amplifier oscillograph, are an essential feature of the present work. They show that the conductivities of both oil and paper for the time intervals comparable with the alternating cycle are, in general, functions of the time and of markedly different values to those pertaining to longer time intervals. Moreover, as we have

shown in an earlier paper,[1] these short-time current curves may be used to predict accurately the alternating current loss, through the empirical derivation of the equations of the curves and the application of the method of von Schweidler. This method of analysis and the separation of the irreversible or conduction component, from the reversible or absorption component of the loss, which it permits, is also an essential feature in the studies reported in this paper.

For a more complete description of the specimens and their method of assembly for the measurements, and particularly for a description of the method of analyzing the oscillograph records, and computing the losses, the earlier papers[1,2,3] may be consulted.

In the following description of the results, the dry paper specimens are designated by the letter A, oil specimens by the letter B, and impregnated specimens by the letter C, a numeral following in each case. The same numeral applies to the component paper and oil of the corresponding combination. For example A-8 and B-8 are combined to form C-8.

FIG. 3

## THE OILS

In Table I are given brief descriptions and the principal physical characteristics of the 10 different samples of oils which have been studied. The oils were furnished by four different well known manufacturers of insulating oils. All of them except B-8 and B-13 are those oils commonly spoken of as being of paraffin base. B-4, B-6, and B-7 are three samples of the same oil, in the original condition, and in two stages of deterioration by oxidation. The results with these three oils have been described in some detail in the paper[2] by Whitehead and Kouwenhoven, cited above. A similar relation exists among the three samples, B-15, B-16, and B-17. B-10 is a well known oil for solid cables and in B-14 it is mixed with rosin (abietic acid) in the ratio 3:1. B-8 is a highly refined very thin white oil whose basic nature is not given. B-13 is a semi-refined oil of naphthenic base. As will be seen, the group presents a fairly wide range of viscosity.

*Conductivity.* Typical short time charge and discharge current curves, as observed with continuous voltage are shown in Figs. 1, 2, and 3, for oils B-15, B-16, and B-17. Additional examples of these curves and the methods of deriving the equations for oil B-7 are given in the Whitehead and Baños paper.[1] The results for the principal oils of the group here studied have been plotted from the oscillograms on double logarithmic scales in Fig. 4. These results show that a principal characteristic of all these oils is an initial conductivity which, in most cases, has a constant value over a period of one second. Thereafter the current falls off more or less rapidly and this initial constant conductivity in some cases may be several hundred times as high as the conductivity measured say after a minute or more. More commonly, however, this ratio is much lower as shown in Table II. The tendency of increasing conductivity, either as the result of oxidation or temperature elevation, is to lower the ratio of the initial to the final conductivity. For example, in oil B-17, with conductivity increased some 250 times by oxidation, the conductivity at $10^4$ seconds differs very little from the initial value during the first one second. The variation with temperature of the initial constant conductivity is shown in Fig. 5. This conductivity is independent of the voltage in the range studied, with some indication of an increase with voltage for temperatures above 60 deg.

TABLE II—COMPARISON OF OIL SPECIMENS
Variation with Temperature of Ratio $\lambda_i/\lambda_f$, Initial Constant Conductivity $\lambda_i$ to 40-Min Conductivity $\lambda_f$ at 1,500 Volts D-C

*$\lambda_i$ too small to detect.

Oils B-7, B-8, and B-15 all show an initial decaying value of charging current over the interval of the first few thousandths of a second, as already reported in an earlier paper.[1] This phenomenon in the case of B-7 seems to be of the nature of reversible absorption since it is accompanied by a discharge curve on short circuit of similar character. Under certain circumstances, the discharge curve seems to be exactly equal and opposite to that portion of the charging current curve which lies above the longer initial horizontal portion. In other cases (B-8 and B-15) the corresponding short initial discharge seems to be absent. In general this initial brief current decay seems to be more pronounced in the lower conductivity oils (B-8 and B-15), although it also appears in slight measure in oil B-7 of much higher conductivity. This feature of the curves is also usually obscured by increasing conductivity, as shown in the earlier paper for oil B-7 with increasing temperature, and here for oils B-16 and B-17 with increased conductivity due to oxidation.

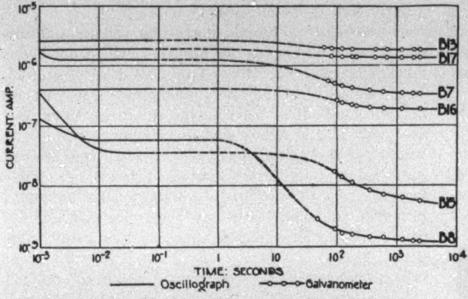

FIG. 4—COMPARISON OF OIL SPECIMENS

Variation with time of charge current at 1,500 volts, 60 deg C

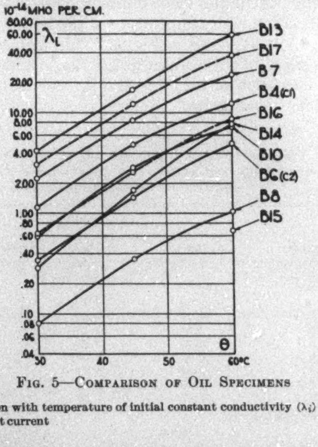

FIG. 5—COMPARISON OF OIL SPECIMENS

Variation with temperature of initial constant conductivity ($\lambda_i$) at 1,500 volts direct current

It is possible that this initial absorption is present to some extent in all oils of these classes. We have found that when it is not present on the oscillograms, the alternating loss is completely accounted for by the conductivity as determined from the initial horizontal or constant-current value. On the other hand, when the initial absorption is present, due account must be taken of it in computing the a-c losses from the d-c characteristics as described in the earlier paper.[1]

The discharge curves are of great interest. So far as their initial sharply decaying region is concerned, they seem to indicate that liquids may show dielectric absorption, for which there has been no evidence heretofore. The later regions of the discharge curve show a very much more gradual decay and are probably associated with the slow movement of space charges carried by larger types of ion.

*Power Factor and Loss.* The power factor temperature relation for the oils is shown in Fig. 6, the electric field intensity being 10,000 volts per cm (approximately 25 volts per mil). The general correlation as between the initial constant conductivity, as shown in Fig. 5, and power factor, is evident as shown in Fig. 6. In all cases except those showing initial decaying charging current large as compared with the subsequent constant value, the latter accounts completely for the dielectric loss. An exception is to be noted for the oil B-14. This is the 3:1 oil-rosin mixture. The minimum in the power factor-temperature curve for this oil, marks the temperature region in which the viscosity is changing rapidly. In this state, the power factor is due almost entirely to dielectric absorption, the contribution of the initial constant conductivity becoming less and less; at 30 deg it cannot be measured. The power factor-temperature relations for oil B-10 and rosin B-9, which in combination form the oil B-14, are shown in

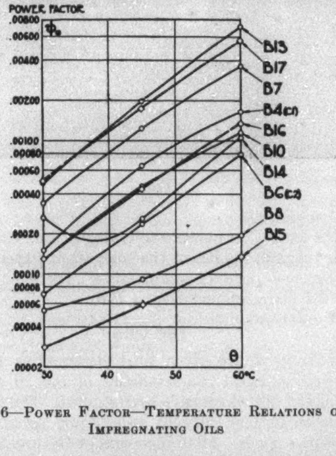

FIG. 6—POWER FACTOR—TEMPERATURE RELATIONS OF IMPREGNATING OILS

Fig. 7. Values of dielectric loss as related to power factor, as measured and as computed from the continuous current charge and discharge curves for oils B-6 and B-7 show[3] that the initial constant conductivity together with the initial absorption (if present) account completely for the total loss.

*Conductivity and Viscosity.* The conductivity of dielectric liquids is ionic in character and the value of the conductivity depends on the number of ions present and on their mobilities or specific velocities. For ions of a given size the mobilities are in general, inversely proportional to the viscosity. This relationship is shown for the various oils under study in Fig. 8 in which are plotted the variation with temperature of the viscosity $\eta$ in poises, and the conductivity $\lambda_o$ in mhos per cm. For convenience, we have used the effective conductivity, assuming that the loss is wholly due to conduction. As already stated, this effective conductivity $\lambda_o$, is identical with the initial constant conductivity as taken from the short time continuous current charging curve, in all oils except those showing appreciable brief initial decay of charging current. In Fig. 9 are plotted the variation with temperature of the product $\eta\lambda_o$ of viscosity and effective conductivity. It will be noted that this product for each oil is roughly constant over the range of temperature 30 deg to 60 deg. Since the conductivity is directly proportional to the number of ions present and inversely proportional to the viscosity, the product $\eta\lambda_o$ is an indication of the number of free ions present. We have then, in this product, a property of the oil which is independent of the temperature. It will be seen that the oils differ markedly as related to the value of this quantity. Obviously, it is not to be expected that the value of $\eta\lambda_o$ should remain constant over any very great range of temperature. In the lower range, as the oils tend to stiffen, it is probable that the inverse relationship between mobility and viscosity does not hold. In the upper range of temperature it is probable that further new ions are generated. The interesting feature here is that we have a quantity which is more or less constant over the operating range of temperature for any one oil and the values of which, over the different oils studied, vary through quite a wide range. We may think of the number of free ions present as to some extent a measure of the purity of the oil. Thus the oil B-8 is probably the most carefully refined of all the oils studied. In contrast with it is oil B-15. The latter oil has a lower value of effective conductivity than oil B-8, yet it is seen that the number of free ions

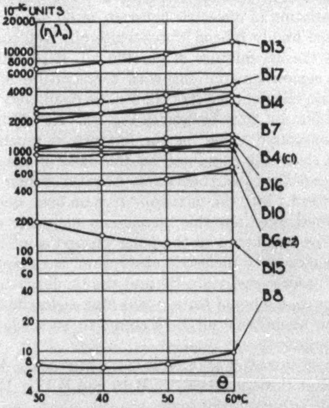

FIG. 9—VARIATION WITH TEMPERATURE OF THE PRODUCT OF VISCOSITY AND EFFECTIVE CONDUCTIVITY ($\eta\lambda_o$) FOR THE IMPREGNATING OILS

present, as indicated by the product $\eta \lambda_o$ is many times greater than that pertaining to oil B-8. This difference is reflected in other ways. We shall in fact, see later on, that this quantity has a direct relationship to the losses in the impregnated paper.

*Dielectric Constant.* The dielectric constant may be computed directly from the alternating charging current. The variations of the dielectric constant $K_o$, and also of the specific gravity $\rho$ for all of the oils studied are shown in Fig. 10. It will be noticed that in general, the variation of the dielectric constant with temperature and as among the various oils, follows the variations in density as it should. The extreme range of variation of dielectric constant at 60 deg is from 2.1 for the highly refined water-white oil, B-8, to 2.48 for B-14 the 3:1 mixture of paraffin oil, B-10, with rosin. The separate variations with temperature of the dielectric constant for this oil, for the rosin, and for their combination, may be seen in Fig. 11. As will be noted, the measured value for the mixture is much greater than the value computed on the basis of the separate values of the constituents and the ratio of their volumes as entering into the mixture. It is an open question as to whether or not this increase in dielectric constant is to be attributed to the polar properties of the rosin molecules or to dielectric absorption as caused by the greatly increased viscosity and the tendency to a solid rather than a liquid state.[4] The high dielectric constant of the naphthenic oil B-13 seems to be accounted for by its density.

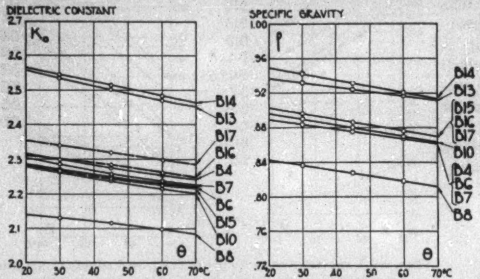

FIG. 10—VARIATION WITH TEMPERATURE OF DIELECTRIC CONSTANT ($K_o$) AND SPECIFIC GRAVITY ($\rho$) OF IMPREGNATING OILS

Another matter of interest is the increase in dielectric constant through oils B-15, B-16 and B-17. These oils are all originally the same, the first B-15, in pure degassed condition and B-16 and B-17 oxidized by bubbling with air at high temperature (105 deg C). It will be seen that this process of oxidation has resulted in an increase of the dielectric constant. There is no corresponding change in either the density or the viscosity of these three oils, and so the increase in dielectric constant must be attributed to other causes. A possible explanation would be a polarized condition of the carbon particles formed by oxidation, as the result of an unsymmetrical adsorption of ions, or a similar behavior as a result of the appearance of colloidal properties. If either of these explanations is correct, the phenomenon should be reflected in the charge and discharge current oscillograms as an initial decaying charge or discharge current. Such curves actually have been observed as indicated above. On the other hand, it is possible to compute from the observed curves the contribution of these initial decaying portions to the final measured dielectric constant. Such computations indicate that the contribution to the total dielectric constant is very much smaller than the actual change in values reported above. The question, therefore, remains an open one and is a promising problem for further experiment.

## THE PAPER

A single grade of wood pulp paper has been used throughout all of the experiments. It was of the type commonly described as "kraft," used in large quantities by a prominent cable manufacturer and furnished by a well known paper manufacturer. It was in the form of tape 2.5 cm wide and 0.1 mm thick. Its specific gravity was about 1.0 and its air resistance 640 seconds.

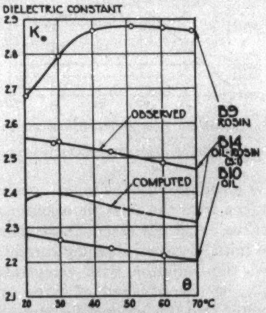

FIG. 11—VARIATION OF DIELECTRIC CONSTANT WITH TEMPERATURE

For rosin (B9), oil (B10) and their 1:3 mixture (B14)

In view of the wide variation of the electric constants of paper with the amount of residual moisture, the assembled capacitor before impregnation was dried and evacuated at 0.1 mm hg pressure and 105 deg C. By variation of the time under these conditions and by frequent conductivity measurements, all paper samples were brought to a standard value of final conductivity of approximately 1.6 x $10^{-15}$ mhos per cm. Considerable variation as among different samples in

| Average | 104.6 | $2.23 \times 10^{-15}$ | 60.1 | 0.00230 |

the measured values of this final conductivity was encountered, as shown in Table III; but in view of the very low order of magnitude of the conductivity, the values given may be taken as indicating a fairly uniform condition of the paper as regards moisture. Moreover these values indicate that the paper was extremely dry. The approximate uniformity over the whole range of specimens is also indicated by the relatively small variation in the values of the power factor of the dry paper specimens as shown in the last column of Table III.

*Loss and Power Factor.* Paper of this type, even in the extremely dry condition, shows a pronounced dielectric absorption as may be seen from the oscillograms of charge and discharge currents shown in the earlier papers.[1] This means that under alternating stress the paper shows dielectric loss and power factor far in excess of values based on the final conductivity alone. The agreement of computed and measured losses for the paper alone have also been given in the earlier papers. In Figs. 18 to 24 the variation with temperature of the dielectric loss for the dry paper is indicated for each specimen in its relation to the loss in the oil and the subsequent loss in the impregnated specimen. The general shape of the temperature power factor curve for paper may be seen in Figs. 15 to 17.

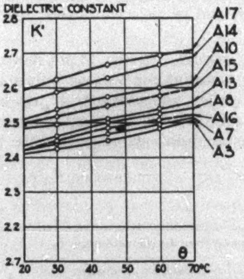

FIG. 12—DIELECTRIC CONSTANT—TEMPERATURE RELATIONS OF DRY PAPER SPECIMENS

*Dielectric Constant.* The measurements of dielectric constant of oil, of paper, and of impregnated paper have permitted the computation of the dielectric constant of wood pulp fiber and also the relative volume in which the oil combines with the paper, as follows:

$K'$ = dielectric constant of dry paper specimen. (paper + air space.)

$K''$ = dielectric constant of impregnated paper specimen. (paper + oil.)

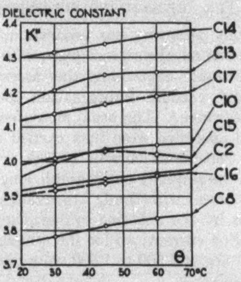

FIG. 13—DIELECTRIC CONSTANT—TEMPERATURE RELATIONS OF IMPREGNATED PAPER SPECIMENS

$K_o$ = dielectric constant of impregnating oil.

$K_p$ = dielectric constant of solid paper fiber.

$m$ = volume ratio, paper to air, and paper to oil.

$$\sigma = \text{"paper constant"} = \frac{m}{K_p}.$$

We have then the following relations for a two layer dielectric, and which are assumed to hold for the combination of paper and oil:

$$K' = \frac{(1 + m)\, K_p}{m + K_p} = \frac{1 + m}{1 + \sigma} \tag{1}$$

$$K'' = \frac{(1 + m)\, K_o K_p}{m K_o + K_p} + \frac{(1 + m)\, K_o}{1 + \sigma\, K_o} \tag{2}$$

For every set of specimens, the quantities $K'$, $K''$, and $K_o$ are all measured directly. Using the foregoing equations we may thus compute the values of $K_p$, $m$, and so $\sigma$. These values are shown in Table IV with the probable error indicated as based on the average of nine sets of values. It is seen, therefore, that for uniform winding, drying, and impregnating conditions, the quantity, $\sigma = \dfrac{m}{K_p}$ appears as a constant of the paper which is independent of the temperature. The variation with temperature of the dielectric constant $K'$ of the dry paper specimen itself is shown in Fig. 12.

TABLE IV—VARIATION WITH TEMPERATURE OF AVERAGE PAPER CONSTANTS

| | Average paper constants | | | Dielectric constant of dry paper dielectric | |
|---|---|---|---|---|---|
| Temp. deg C | Volume ratio Paper: Air Paper: Oil | Dielectric constant of solid paper fiber | Ratio: $m/K_p$ | Observed average of nine specimens | Computed from average constants |

| 60 | 2.90 ± 0.12 | 5.60 ± 0.10 | 0.518 ± 0.024 | 2.56 ± 0.05 | 2.57 |

## THE IMPREGNATED SPECIMENS

Immediately following the separate measurements on paper and on oil, the oil was drawn into the vacuum temperature tank containing the assembled paper capacitor and vacuum impregnation took place as described elsewhere.[2] The usual measurements on the impregnated specimen were then carried out; that is, short time continuous current charge and discharge curves, with the amplifier-oscillograph, long time steady continuous current with the D'Arsonval galvanometer; power factor by the Schering bridge; and total alternating charging current; all for the temperature range 30 deg to 60 deg and 500 to 1,500 volts continuous and alternating voltages.

Impregnated paper shows the phenomenon of dielectric absorption and residual charge in marked degree. The oscillographic records of charge and discharge current, as shown in the earlier papers, readily permit the computation of the equations of the charge and discharge currents, and so the further computation of that portion of the total dielectric loss which is due to dielectric absorption. The difference between the charge and discharge curves permits computation of the conductivity and of the loss arising therein. The sum of the losses thus computed from the d-c measurements has been found throughout to be in excellent agreement with the direct measurement of the loss on the Schering bridge. An example of this agreement is shown in Table V giving a summary of the measurements and computations on the three impregnated specimens, C-15, C-16, and C-17. These three specimens were impregnated with the oils B-15, B-16, and B-17, which, it will be recalled, are basically the same, B-16 and B-17 representing two stages of deterioration by oxidation. A better picture of the influence of this deterioration on the electrical behavior of the impregnated paper will be seen in Figs. 15 to 17, and 21 to 23. The chief interest in Table V is to indicate those quantities which are measured and those which are computed, and the close agreement between the alternating loss as measured, shown in the fifth column, and the same loss as computed from the d-c measurements, as shown in the last column. The computed losses are the sum of those due to reversible absorption and to irreversible conduction.

The general nature of the influence of the properties of the paper and of the oil on the impregnated product may be studied with greatest advantage from the standpoint of the changes in dielectric constant, in power factor, and in dielectric loss as related to temperature.

*Dielectric Constant.* In Fig. 13 are shown the values of dielectric constant for various impregnated specimens as related to temperature. It will be seen that in general, the dielectric constant increases with increasing temperature, showing in this respect the

influence of the paper as seen in Fig. 12 rather than of the oil whose dielectric constant decreases with increasing temperature, as shown in Fig. 10. Note that in Fig. 13 the influence of the paper is also seen in the relative positions of specimens C-15, C-16, and C-17, as compared with the corresponding paper specimens. There is no obvious explanation of the slight differences as among these three paper specimens other than possible slight variations in the conditions of assembly. The values of $K''$ indicated in Fig. 13 together with the values of $K'$ given in Fig. 12 were those used for computing the values of $K_p$, the dielectric constant of solid paper fiber, and the other constants given in Table IV.

The general comparison of the curves of Figs. 12 and 13 suggests at once that variations in the dielectric constant of the impregnated samples are largely determined by the dielectric constant of the oil. It is in accord with general experience that the dielectric constant of impregnated paper may be computed from the values for the separate constituents when their relative volumes in the impregnated sample are known. From equations (**1**) and (**2**), it may be readily seen that the increase in dielectric constant, brought about by impregnation, expressed as a ratio is:

$$\frac{K''}{K'} = \frac{(1+\sigma)\,K_o}{1+\sigma\,K_o} \qquad (3)$$

or expressed as a percentage change:

$$\frac{\Delta K}{K'} = \frac{K_o - 1}{1+\sigma\,K_o} \qquad (4)$$

in which $\Delta K = K'' - K'$

In either case, it is seen that for uniform conditions of winding, drying and impregnation of a given paper, the increase in dielectric constant at a given temperature is a function of the dielectric constant of the oil $K_o$ only. Since the paper constant $\sigma$ is approximately independent of the temperature, equations (**3**) and (**4**) must therefore hold for all temperatures. In Fig. 14 the drawn curves, showing the increase of dielectric constant on impregnation as a function of $K_o$, the dielectric constant of the impregnating oil, were computed using the values of $\sigma$ given in Table IV and the equations (**3**) and (**4**) above. The measured values are indicated in the small circles. The independence to temperature of this relationship is shown by the practical coincidence of the curves for the three temperatures, 30 deg, 45 deg, and 60 deg. The excellent agreement between computed and observed values of the increase of the dielectric constant on impregnation confirms the assumption that the formulas for a two-layer dielectric apply equally to the mixture of the oil and paper. This leads to the further certainty that in well impregnated paper, practically all of the space originally occupied by air in the dry paper specimen becomes completely filled with oil after impregnation. These facts are the underlying basis of the use of measurements of capacitance as related to pressure variations during manufacture, as a measure of the degree of impregnation of high-voltage cables. If air is present in any considerable amount, as in air patches, bubbles, etc., the dielectric constant changes with pressure. On the other hand, if the paper is thoroughly impregnated no such variation is to be expected. It may be said in passing, however, that there is much evidence of a varying degree of completeness of impregnation which seems to lie below the range which may be detected by changes in dielectric constant. There is a range of condition in which residual air or moisture in amounts too small to occupy any substantial proportion of the total volume, may yet vary widely and have an important bearing on the degree of impregnation and the resulting life of the insulation under prolonged stress.

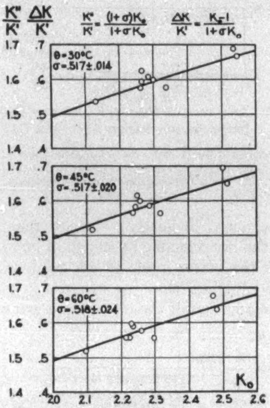

FIG. 14—INCREASE IN DIELECTRIC CONSTANT WITH IMPREGNATION AS A FUNCTION OF $K_o$, THE DIELECTRIC CONSTANT OF THE IMPREGNATING OIL

*Power Factor*. The general influence of the separate constituents, paper and oil, on the final product in the matter of power factor, is indicated in Figs. 15, 16, and 17, in which the power factor temperature relations are plotted for the three specimens, C-15, C-16, and C-17, and also in the data in Table V. In the figures the lowest curve $\psi_o$ gives the power factor temperature relation for the oil alone. The curve $\psi'$ gives the corresponding curve for the paper, and the curve $\psi''$ that for the impregnated specimen. The intermediate curve $\psi_r''$ is computed from the d-c charge and discharge curves. The difference at any one temperature between the curves $\psi'$ and $\psi_r''$ represents the increase in power factor due to reversible absorption and this difference is designated as $\Delta\psi_r$. This is the component of the increase in $\psi$, over that of the paper alone, which is due to reversible absorption. The remainder of the increase $\Delta\psi_i$ is the increase in power factor due to conduction of the oil, and which is spoken of in these papers as the irreversible conduction of the impregnated paper.

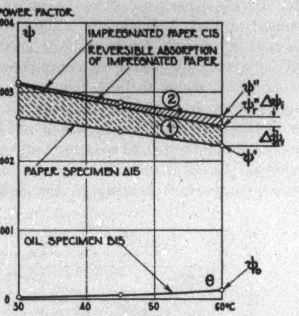

Fig. 15—Analysis of Power Factor at 1,500 Volts. Impregnated Paper Specimen C15

Increase in power factor due to impregnation:
(1) Increase in reversible absorption: $\Delta\psi_r$
(2) Contribution of irreversible conduction: $\Delta\psi_i$

It will be noted in general, that of the total power factor of the impregnated specimen, a large proportion of it with the better grade of oils used, is due to the paper; and further, that the increase in power factor due to the addition of the oil is much greater than the

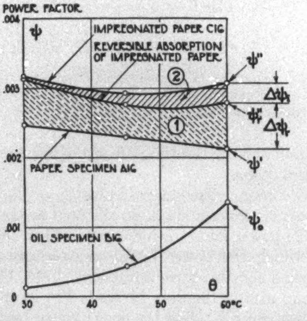

Fig. 16—Analysis of Power Factor at 1,500 Volts. Impregnated Paper Specimen C16

Increase in power factor due to impregnation:
(1) Increase in reversible absorption: $\Delta\psi_r$
(2) Contribution of irreversible conduction: $\Delta\psi_i$

sum of the values of the power factor of paper and of oil. This latter is a well known result of a combination of two dielectrics within the same capacitor and is in qualitative accordance with Maxwell's theory of dielectric absorption. With increasing conductivity of the oil as indicated in Figs. 16 and 17, the components $\Delta\psi_r$ and $\Delta\psi_i$, the increases due to reversible absorption and irreversible conduction respectively, increase substantially, so that as the conductivity and the power factor of the oil itself increase, their influence on the impregnated specimen finally becomes greater than the influence of the paper.

*Dielectric Loss.* The foregoing curves tracing the behavior of power factor before and after impregnation are plotted directly from the measurements. A more striking picture of these changes, however, is afforded by expressing the results in terms of dielectric loss. This is readily accomplished through the measurements of voltage, power factor and total charging current. In Figs. 18 to 24 are shown the relation between dielectric loss and temperature for seven of the total of ten specimens which have been studied. Each figure shows the loss in the oil $W_o$, the loss in the dry paper $W'$, and the loss in the impregnated specimen $W''$, all based on direct measurements. The curve $W_r''$ is also included giving the computed separation of the total increase of loss over that of the paper, into the two components $\Delta W_r$ and $\Delta W_i$, due to reversible absorption and irreversible conduction respectively. Fig. 18 shows the influence of the thin water white oil, B-8. This was one of the purest oils of the group, having initially very low conductivity and power factor. It is seen that in spite of the low conductivity of the oil, and the low value of $\Delta W_i$, the loss due to absorption $\Delta W_r$ (area "1") is quite large. Fig. 19 shows the influence of a well known cable oil, B-10, and Fig. 20, the effect of mixing rosin with oil B-10. As seen, the addition of the rosin causes a substantial increase in the loss $\Delta W_r$, and shifts the temperature of minimum loss to lower values. It has been seen in Fig. 13 that rosin

(2) Contribution of irreversible conduction: $\Delta\psi_i$

has also a very pronounced influence on the dielectric constant. Figs. 21, 22, and 23 show the influence on power loss of progressive deterioration as found in specimens C-15, C-16, and C-17. Other data on these specimens have been given in connection with Table V and Figs. 15, 16, and 17. The pronounced influence of the changes in the oil is at once evident, and we discuss it further below. Fig. 24 is included because of the special interest attaching to oil B-13, the semi-refined oil of naphthene base. As will be seen, this oil has an exceptionally high conductivity, which is reflected in pronounced degree in the impregnated specimen. The values of loss and power factor shown for this oil could not be tolerated in insulation for high voltage. The oil, however, has other interesting properties, notably in the matter of stability under high stress, which are to be described in another paper.

## DISCUSSION

The chief purpose of these studies has been to find, if possible, some definite relationship or correlation between the properties of the basic constituents, paper and oil, and those of the impregnated paper. As stated at the outset, the electrical properties of both paper and oil are highly complex, and even anomalous, and as a consequence, the application of such theories as we have for mixtures of dielectrics, is practically impossible because the usual normal constants of materials invoked in theoretical discussion, cannot be evaluated. Dry paper itself shows pronounced dielectric absorption and the oils generally show a conductivity varying with the time. What values, therefore, of dielectric constant and conductivity are to be selected for each in an effort to apply, for example, Maxwell's theory? We have made many efforts to find constants of the two materials which might be used, but in all cases, the results are roughly qualitative only, when an effort is made to predict the behavior of the impregnated material.

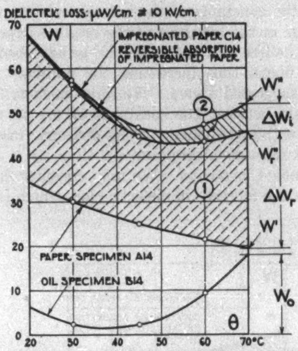

FIG. 20—ANALYSIS OF DIELECTRIC LOSS AT 10 KV PER CM. SET 14 IMPREGNATED WITH 3:1 MIXTURE OF OIL B10 AND ROSIN

Increase in dielectric loss with impregnation:
(1) Increase in reversible absorption: $\Delta W_r$
(2) Contribution of irreversible conduction: $\Delta W_i$

We are forced, therefore, to seek some empirical relationship, and here the effort to trace a correlation of properties before and after impregnation has been much more successful. This correlation has been possible only through the separation of the increase of loss in the impregnated specimen into its two constituents through the oscillographic measurements of the short time charge and discharge curves.

Before impregnation, the dielectric loss in dry paper is entirely due to reversible absorption. The charge and discharge curves are almost exactly equal and opposite to each other. The loss due to irreversible conduction in dry paper is so small as to be entirely negligible as compared to that due to reversible absorption. The exact origin or cause of dielectric absorption in paper is a most interesting unsolved question. In the author's opinion, it must be associated with the surface conditions over the network of cellulose fibers, over which surfaces there must be an assemblage of ions with greater or less freedom of movement, arising in the residual moisture and air. It is not necessary to pursue this picture further than to point out that it may readily be invoked to explain the decaying charge and discharge curves, a polarization in addition to that due to the solid cellulose structure, and a very low value of final or long time conductivity as measured under continuous potential. When the oil enters the paper it is obvious that these surface conditions will be changed and that there must be some relationship between the constants of the impregnating liquid and the change in the behavior of the original paper. For example the free ions in the oil may be adsorbed by the cellulose fibers, thus increasing the numbers already there as suggested above. We have in fact, found a relationship between the constants of the oil and the increase in the component of the dielectric loss which is due to reversible absorption.

Increase in dielectric loss due to impregnation:
(1) Increase in reversible absorption: $\Delta W_r$
(2) Contribution of irreversible conduction: $\Delta W_i$

*Irreversible Conduction.* We may consider first that portion of the increase in dielectric loss which is due to irreversible conduction. The difference between the charge and discharge curves of any composite dielectric usually has a constant value commonly attributed to the normal conductivity of the material. Impregnated paper behaves in this manner. The impregnation of the paper introduces the element of irreversible conduction as shown in the various curves above in the upper areas "2". In view of the negligible value of this component in the dry unimpregnated paper, it is evident that the presence of irreversible conduction in the impregnated paper must be due to the oil. This component is, therefore, a pure conduction phenomenon and may be thought of as a straight leakage through the impregnated specimen; in other words, the leakage afforded by oil paths in which there are no barriers due to the paper structure. The phenomenon is probably not actually so simple; however, the effect is due to an average total ionic movement in many separate paths permitting free ionic motion. If this picture is correct, the irreversible conduction loss which appears on impregnation should be proportional to the conductivity of the impregnating oil $\lambda_o$. That this is true is clearly shown in Fig. 25 in which the quantity $\Delta W_i$ is plotted in relation to $\lambda_o$ the effective conductivity over the whole range of oils studied, and over the temperature range 30 deg—60 deg C for each oil.

*Reversible Absorption: Correlation with Conductivity of Oil.* It has been more difficult to find a correlation between that portion of the increase in dielectric loss $\Delta W_r$, due to reversible absorption, and the basic properties of the oils. For any one oil there is a definite relationship between $\Delta W_r$ and the conductivity over the temperature range studied. This relationship is shown for four of the oils in Fig. 26 which indicates that the quantity $\Delta W_r$ for any one oil when plotted against the conductivity of the oil forms a smooth curve. For the high conductivity oils C-13 and C-17, the relationship is approximately linear. For oils of moderate conductivity, C-7 and C-10 $\Delta W_r$ is practically independent of the oil conductivity $\lambda_o$ over a wide temperature range. The points pertaining to the lower conductivity oils C-8 and C-15 have not been plotted in order to avoid confusion. These points all lie close to the ascending portion of the curve for C-10. For all the specimens as the oil conductivity $\lambda_o$ is carried to low values as for example, through the lowering of temperature, it is seen that $\Delta W_r$ increases. This is a well known property due to reversible absorption and is in quantitative accord with the Maxwell-Wagner theory of dielectric absorption. It is also seen in Fig. 26 that the points on the different curves corresponding to any particular value of temperature themselves lie on a smooth curve. The explanation of this fact is not entirely obvious. However, it may be noted that the purer the oil and the lower its conductivity, the lower the value of $\lambda_o$ at which the curves turn upward. This relationship will have the tendency to throw the values of $\Delta W_r$ for the different oils at say 30 deg on a smooth curve. The fact that the values for any higher temperature also fall on a smooth curve then becomes only an indication that the law of increase of conductivity with temperature is the same for all the oils.

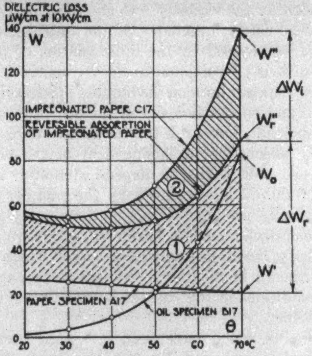

Fig. 23—Analysis of Specific Dielectric Loss at 10 Kv per Cm Impregnated Paper Specimen C17

Increase in dielectric loss due to impregnation:
(1) Increase in reversible absorption: $\Delta W_r$
(2) Contribution of irreversible conduction: $\Delta W_i$

*Reversible Absorption: Correlation with Ionic Density of Oil.* We have sought, however, for a wider correlation between the properties of the impregnated product and the properties of the impregnating oil. Since one type of paper is used and in an approximately uniform condition throughout, it would appear that it should be possible to tie in the electrical behavior of the impregnated product in all cases with some single property or constant of the respective oils. It is obvious from the results described in the foregoing paragraph that the conductivity of the oil will not serve for this purpose, each oil showing a different curve. We have, therefore, looked to the properties of surface tension and viscosity as these obviously have a direct bearing on the degree of penetration of the oil into the paper. The values of these quantities alone did not appear to lead to any promising correlation. However, it was immediately found that the product of the viscosity $\eta$ and effective conductivity $\lambda_o$ led to an interesting uniform relationship. As indicated in the earlier part of the paper this product is a measure of the number of free ions present in the oil and therefore, may be taken as an index of the "electrical purity" of the oil. In Fig. 27 we have plotted the relationship between the increases in power factor $\Delta\psi_r$ and dielectric loss $\Delta W_r$ due to reversible absorption, in their relation to the product $\eta\lambda_o$ for all of the oils studied, in their original condition. For the low conductivity oils, the points plotted are the average values for the temperatures 30 deg, 40 deg, 50 deg and 60 deg, the points lying very close together. For the higher conductivity oils, the plotted points correspond to different temperatures. It will be seen that there is a remarkable relationship between the increase of loss due to the reversible absorption and the product of the viscosity and conductivity among all oils in the normally pure and undeteriorated condition. Plotting points for a variety of oils and at different temperatures results in a smooth curve.

A similar relationship exists over the extreme range of conductivity afforded by the three oils B-15, B-16, and B-17, which it will be recalled are all the same oil, the first stage undeteriorated and two other stages of increased deterioration due to oxidation. This gives three basic differences in conductivity at 30 deg in the relationship 1 to 5 to 20, with a further extension of range of the product $\eta\lambda_o$ through temperature variation. Fig. 28 shows the curves between $\Delta W_r$, $\Delta\psi_r$, and $\eta\lambda_o$ for these three oils. It is seen that they are closely similar in shape and in position to those in Fig. 27. In the upper range, however, the curves of Fig. 28 fall

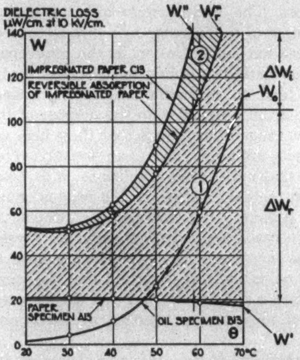

Fig. 24—Analysis of Specific Dielectric Loss at 10 Kv per Cm Impregnated Paper Specimen C13

Increase in dielectric loss due to impregnation:
(1) Increase in reversible absorption: $\Delta W_r$
(2) Contribution of irreversible conduction: $\Delta W_i$

slightly below those of Fig. 27 and so the results for the two groups of oils have been plotted separately.

The curves of Figs. 27 and 28 are of the general type

$$y = a + bx + cx^2 \tag{5}$$

If we attempt to interpret this relationship in terms of the Maxwell theory of absorption, we find the constant term accounted for by the fact that even if the impregnating oil had zero conductivity, there would still be a loss in the combination of oil and paper due to reversible absorption. The linear term $bx$ indicates that there is a component of the increase $\Delta W_r$ directly proportional to the free ion concentration in the impregnated oil. As the conductivity reaches higher values we find this increase, due to reversible absorption, rising more rapidly than in proportion to the number of free ions. An obvious suggestion here is that these high values of conductivity are usually due to an elevation of temperature and that under these conditions, it is possible to picture an actual increase in the original number of free ions present. It is furthermore evident that this type of increase would be less rapid for those oils in which the increase of conductivity has been brought about by oxidation. It is certain that the ions in this case are larger and heavier and that the increase in the number of ions due to temperature elevation would be less.

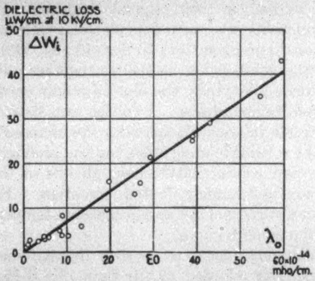

FIG. 25—DIELECTRIC LOSS DUE TO IRREVERSIBLE CONDUCTION ($\Delta W_i$) AS A FUNCTION OF THE CONDUCTIVITY ($\lambda_o$) OF IMPREGNATING OILS

Our knowledge of the origins or causes of dielectric absorption in dry paper, and the data at present available, do not seem to warrant any extensive effort at any explanation of the relationship between the properties of the oil and those of the impregnated paper which has been shown above. In the foregoing the behavior of dry paper under continuous potential has been attributed to the adsorption by the surfaces of the cellulose fibers of electrolytic ions arising in residual air and moisture. This picture assumes a limited movement of such ions under electric stress and a resulting contribution to the total polarization of the structure. If it can be assumed that on impregnation the free ions which are present in the oil join, through the processes of adsorption, those ions which have already been taken up by the surfaces of the paper structure before impregnation, we have at least a tentative picture which is in accord with the facts. That is, the increase in loss due to irreversible absorption would be proportional to the number of new ions added and we may assume that the motion of adsorbed ions on the surface of the cellulose fibers is different from the motion of ions in the body of the liquid, and so might well be independent of the viscosity. In any event, the following may be safely asserted. Of the total increase in dielectric loss caused by the impregnation of paper a portion of it is proportional to the conductivity of the oil, and so depends both on the number of ions originally in the oil and on the viscosity of the oil. Another and more important portion of the increased loss is due to reversible absorption, is independent of the viscosity of the oil, and seems to depend definitely on the purity of the oil as measured by the number of free ions originally present. While no certain explanation of this relationship can yet be offered, such explanation undoubtedly lies in the particular way in which the oil replaces the air in the finer interstices of the paper and in the conditions in the contact layer between oil and cellulose fiber.

The results which have been presented pertain to one type of paper only. For this reason no effort has been made to evaluate the constants of equation (5) nor to propose a general formula for the predetermination of the losses and behavior of impregnated paper in general. It would however, be a simple matter to write such a formula for the particular paper here studied. It is obvious that the most promising direction for further knowledge of the interesting relationships here brought out would be a continuation of similar studies with the paper as the variable. If such a study could be carried out, it might be possible to evaluate the constants $a$, $b$, and $c$, in formula (5) in terms of the properties of the paper, and so to write down formulas permitting the predetermination of the electrical con-

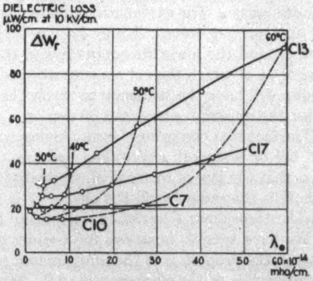

FIG. 26—INCREASE IN DIELECTRIC LOSS ($\Delta W_r$) DUE TO REVERSIBLE ABSORPTION AS A FUNCTION OF THE CONDUCTIVITY OF THE IMPREGNATING OILS ($\lambda_o$)

stants of any paper as impregnated with any oil; in other words, to place the design of impregnated paper insulation on an accurate engineering basis. Unfortunately, the continuation of this work under past conditions is no longer possible. It is hoped, however, that it may be resumed in the not too distant future.

### ACKNOWLEDGMENT

The active prosecution of this work has only been possible through the encouragement, confidence, and financial support of the Utilities Research Commission of Illinois, to whom grateful acknowledgment on behalf of the Johns Hopkins University and of the author of this paper is hereby extended.

Cordial acknowledgment is also made of the enthusiastic and skillful cooperation, in the experiments and in the analysis and preparation of the results, of Mr. A. Baños, Jr., and Dr. S. K. Waldorf. Thanks are also extended to Professor W. B. Kouwenhoven and to other members of the laboratory staff who from time to time have extended helpful cooperation.

### CONCLUSIONS

1. The electrical and other physical properties of 10 insulating oils have been examined. A single grade of paper was impregnated with each of the oils. The electrical properties of the impregnated paper have been studied as related to the original characteristics of the oils.

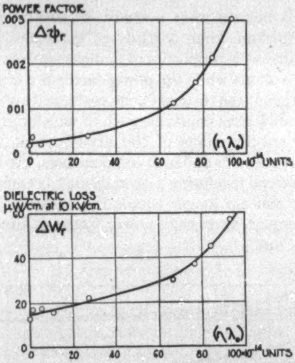

Fig. 27—Increase in Power Factor ($\Delta\psi_r$) and Dielectric Loss ($\Delta W_r$) as a Function of the Product ($\eta\lambda_o$) Specimens Impregnated with Undeteriorated Oils

2. The measurements of dielectric constant permit determination of the relative volume content of oil and of paper fiber in the impregnated specimen, as well as the basic dielectric constant of the fiber itself.

3. The dielectric constant of an insulating oil is increased by oxidation without corresponding changes in density.

4. The dielectric loss in impregnated paper consists of two components, one due to conduction and the other due to dielectric absorption. A general relation exists for all the oils and over the temperature range studied, between each of these components of loss and common physical properties of the impregnating oil.

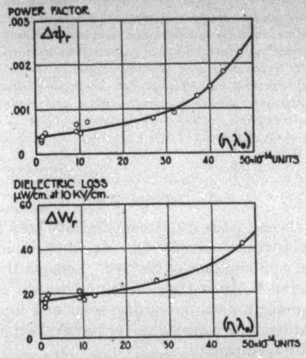

Fig. 28—Increase in Power Factor ($\Delta\psi_r$) and Dielectric Loss ($\Delta W_r$) Due to Reversible Absorption as a Function of the Product ($\eta\lambda_o$), Showing the Effect of Three Stages of Deterioration of Oil B15

5. The conduction loss in impregnated paper is directly proportional to the effective conductivity of the oil regardless of type.

6. The increase on impregnation, of the loss due to reversible absorption, is a definite function of the product of the viscosity and the conductivity of the impregnating oil, regardless of type.

7. The product of viscosity and conductivity is a measure of the free ion content of the oil. It is proposed as a measure of electrical purity of an impregnating oil. The function connecting this quantity with the increase in loss has been determined for one paper. Its determination for other papers should make it possible to write a general expression for the predetermination of the total loss resulting from the impregnation of any type of paper with any type of oil, in terms of the separate properties of each.

# Capacitance and Loss Variations with Frequency
## And Temperature in Composite Insulation

BY HUBERT H. RACE*
Member, A.I.E.E.

***Synopsis.***—*Variations in electrical properties of composite insulation with changes in temperature and frequency are important because they lead to concepts of physical causes of such variations and, therefore, indicate how to obtain improved electrical properties in commercial materials. Typical experimental data are presented showing the capacitance and loss characteristics of synthetic resin laminated materials and of imperfect composite dielectrics made from combinations of fused quartz or glass and semi-conducting liquids. An example is given showing agreement between calculated and observed characteristics of such a glass-liquid combination.*

*Theoretical analyses are given, showing that the general form of the capacitance and loss characteristics could be caused by any one of several physical mechanisms.*

*As a result of these studies it seems probable that in synthetic resin laminated products semi-conducting materials in small insulated pockets or fibers can account for observed characteristics and can be represented mathematically by the Maxwell-Wagner theory. It is also shown that capacitance and loss measurements at one frequency and temperature cannot generally be used to predict corresponding values under different conditions.*

---

### A. INTRODUCTION

FOR several years measurements have been made on a wide variety of materials, including liquids, solids and combinations of the two. Some of the results on liquid dielectrics have been published,[1] and this paper[2] presents data on certain solid and liquid-solid combinations with suggestions for physical explanations of the observed results.

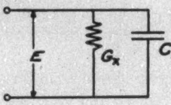

FIG. 1—PARALLEL CIRCUIT EQUIVALENT TO SAMPLE

Kirch[3] in a recent series of articles also emphasizes the extreme importance to design engineers of such studies because of the need for clarifying physical explanations of observed phenomena. A knowledge of the causes and mechanisms responsible for either desirable or undesirable properties will indicate how the first may be obtained and the second eliminated or at least reduced.

### B. ELECTRICAL CHARACTERISTICS OF EXPERIMENTAL MOLDED MATERIALS

It has been found convenient to interpret all measurements in terms of the equivalent parallel circuit shown in Fig. 1. The complex expression for the reciprocal impedance of the measuring circuit is given by the relation

$$Z^{-1} = G_x + i\omega C_x = \omega C_v(\epsilon'' + i\epsilon') \qquad (1)$$

in which

$G_x$ = the equivalent parallel conductance of the sample
$C_x$ = the equivalent parallel capacitance of the sample
$\omega = 2\pi f$, where $f$ = electrical frequency in cycles per second
$i = \sqrt{-1}$
$C_v$ = capacitance of the same geometric arrangement of electrodes in vacuum

For comparative purposes it is convenient to study unit quantities which may be defined by comparing the two forms of equation (1) as follows:[4]

$$\epsilon' = C_x/C_v = \text{dielectric constant} \qquad (2)$$

$$\epsilon'' = G_x/\omega C_v = \text{loss factor} \qquad (3)$$

$$\sin \tan^{-1} \epsilon''/\epsilon' = \text{power factor} \qquad (4)$$

If $\epsilon'$ is not constant a study of variations in $\epsilon''$ is more important than a study of variations in power factor, since $\epsilon''$ is proportional to dielectric loss per cycle per unit volume while the power factor is a trigonometric function of the ratio between coefficients of dielectric loss and dielectric constant, each of which may vary as independent functions of the experimental variables. At low frequencies and high temperatures, the loss angle in commercial insulating materials may become large so that the sine no longer equals the tangent, and $\epsilon''$ is much more accurate than power factor as a measure of dielectric loss.

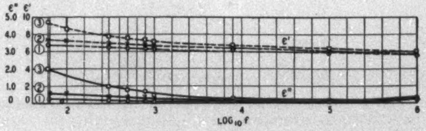

FIG. 2—SPECIAL SAMPLE, PHENOLIC RESIN WITH MICA, BAKED

(1) 30 deg C, (2) 60 deg C, (3) 90 deg C

Typical data[5,6] for experimental phenolic resin compounds having differing ingredients and amounts of cure are shown in Figs. 2 and 3. For the better material, both capacitance and loss are practically independent of frequency at room temperature, but at 90 deg C both show an appreciable increase at low frequencies. This characteristic is greatly accentuated in the uncured

material, in fact the results plotted in Fig. 3 are extremely interesting because they indicate the causes for similar characteristics found on a much smaller scale in the better sample. Data from Fig. 3 for several frequencies are given in Table I as an excellent illustration of the large variations in characteristics observed in poor materials and the advantages of $\epsilon''$ over power factor as a true measure of dielectric loss.

| Frequency cps | $\epsilon'$ | | | $\epsilon''$ | | | P.F. | | |
|---|---|---|---|---|---|---|---|---|---|
| | 60 | $10^3$ | $10^6$ | 60 | $10^3$ | $10^6$ | 60 | $10^3$ | $10^6$ |
| Temp. °C 30 | 12.2 | 10.2 | 7.4 | 2.0 | 0.8 | 0.5 | 0.162 | 0.078 | 0.067 |
| 60 | 19.6 | 11.8 | 7.9 | 9.5 | 2.3 | 0.6 | 0.437 | 0.191 | 0.076 |
| 90 | 45.3 | 16.4 | 8.4 | 30.0 | 7.0 | 0.6 | 0.552 | 0.393 | 0.071 |

The first conclusion from these data is that *loss and capacitance measurements taken at one frequency and temperature can not be used to predict the characteristics at other frequencies and temperatures except under special conditions where the type of variation to be expected is already known.*

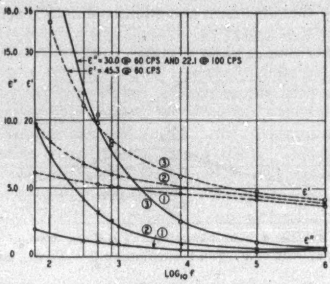

FIG. 3—SPECIAL SAMPLE, PHENOLIC RESIN WITH MICA AND CARBON BLACK, UNBAKED

(1) 30 deg C, (2) 60 deg C, (3) 90 deg C

The second conclusion is that *when $\epsilon'$ is not constant, or the loss angle is large, changes in power factor are not accurate measures of changes in dielectric loss.*

This is especially true at 60 cycles per second; for example, in Table I the loss per cycle per unit volume ($\epsilon''$) increased 15 fold as the temperature increased from 30 to 90 deg C, but the power factor increased less than four fold because the effective capacitance also increased nearly four fold. This has been recognized and the effect has been accounted for by calculating a loss factor by multiplying power factor by dielectric constant[7] but the definition of $\epsilon''$ given by equation (3) seems much more logical and meaningful. The third conclusion is that the physical causes of such large changes are worthy of considerable further study. The following calculations and experiments resulted.

## C. THEORETICAL STUDY

The curves in Fig. 3 appear to be portions of the general curves for an imperfect dielectric having relaxation characteristics: *i. e.,* portions to the right of the frequency for maximum loss in Fig. 4. There are at least three physical mechanisms each of which can give such characteristics. It is conceivable that in the same composite dielectric all three may be important under different frequency and temperature conditions and even that two or all of them might be operative to different degrees under the same conditions.

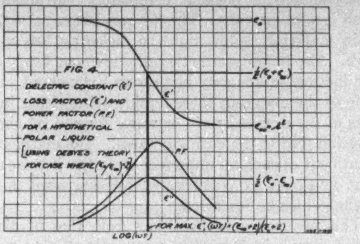

FIG. 4

The three mechanisms are:

A. Orientation of polar particles in a viscous medium.

B. Translation of charged particles, either for relatively long distances, as at low frequencies in a liquid, or for relatively short distances, as at high frequencies in a liquid, or along semi-conducting surfaces of fibrous material, or within semi-conducting cells of a solid.

C. Formation of polarized films or space charges at the electrodes.

Mechanism A seems highly improbable as an explanation of the data in Fig. 3 nevertheless curves showing the general form of the results of this theory[8] are given in Fig. 4.

The equations for the dielectric constant and loss factor of a polar liquid from which these curves were plotted were given in an earlier paper,[1] and it is of particular interest to note the simple relations which hold at the frequency $f_m$ at which the maximum occurs.

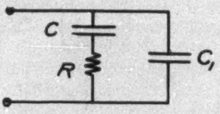

FIG. 5—ONE FORM OF EQUIVALENT CIRCUIT FOR MECHANISM B

Anderson[9] measured capacitance and loss for several solids at high frequencies but was unable to obtain any correlation with Debye's theory.

Such a correlation is not to be expected since the simple theory applies only to dilute solutions. It seems however that the variations found by Anderson are similar to those we have found and can be explained by the Maxwell-Wagner theory, as indicated below.

Mechanism B seems highly probable as an explanation of the data shown in Fig. 3. This is simply stating in a slightly different way the mechanism described by K. W. Wagner[10] in his extension of Maxwell's theory of a layer dielectric. For this particular discussion instead of thinking of a layer dielectric, we visualize minute semi-conducting pockets completely surrounded by good insulating walls. The d-c conduction of synthetic resin materials is low but the dielectric loss may be high. Also before synthetic resins are completely cured, conducting liquids may be present throughout the volume of the material, these liquids being either ingredients of the uncured resin or water formed by chemical reaction during the curing process. The mathematical treatment of such an imperfect dielectric is the same as that developed by Wagner and the behavior is the same as that which he described.

This physical concept differs from that of Murphy and Lowry,[11] in that they assume insulating micelles having semi-conducting surfaces while we picture semi-conducting pockets completely surrounded by insulating walls. Their picture may be true for fibrous materials containing adsorbed moisture while ours may be true for molded or varnish-treated materials. In either case the mathematical equivalent should be the same.

Neglecting d-c conduction caused by continuous current paths from one electrode to the other through an imperfect dielectric, the heterogeneous series and parallel, conductance and capacitance paths can be represented by the equivalent electrical circuit shown in Fig. 5. The reciprocal impedance of this circuit can be expressed as

$$Z^{-1} = \frac{R\omega^2C^2}{1 + R^2\omega^2C^2} + i\left[\frac{\omega(C + C_1) + R^2\omega^3C^2C_1}{1 + R^2\omega^2C^2}\right] \quad (5)$$

Comparing this relation with equation (1) we find the following expressions for the effective dielectric constant $\epsilon'$, loss factor $\epsilon''$ and power factor of such an imperfect dielectric.

$$\epsilon' = \frac{1}{C_v}\left[C_1 + \frac{C}{1 + R^2\omega^2C^2}\right] = \frac{\alpha^2\epsilon_0 + \omega^2\epsilon_\infty}{\alpha^2 + \omega^2} \quad (6)$$

$$\epsilon'' = \frac{1}{\omega C_v}\left[\frac{R\omega^2C^2}{1 + R^2\omega^2C^2}\right] = \frac{\alpha\omega(\epsilon_0 - \epsilon_\infty)}{\alpha^2 + \omega^2} \quad (7)$$

$$PF = \sin\tan^{-1}(\epsilon''/\epsilon') \quad (8)$$

where

$\alpha = 1/RC$ = time constant of circuit

$\epsilon_0 = (C_1 + C)/C_v$ = effective dielectric constant at zero frequency

$\epsilon_\infty = C_1/C_v$ = effective dielectric constant at infinite frequency

$\omega = 2\pi f$

$f$ = frequency in cycles per second

The variations of these coefficients with frequency is shown in Fig. 6 for the case where $C = C_1$.

By taking the first derivative of equation (7) with respect to $\omega$, it may be shown that for the frequency $f_m$ at which maximum loss occurs the following relations hold.

$$\omega_m = \alpha \quad (9)$$

or

$$f_m = 1/2\pi RC = \alpha/2\pi \quad (9a)$$

$$\epsilon_m' = \frac{1}{2}(\epsilon_0 + \epsilon_\infty) = \frac{1}{2}\left[\frac{2C_1 + C}{C_v}\right] \quad (10)$$

$$\epsilon''_m = \frac{1}{2}(\epsilon_0 - \epsilon_\infty) = \frac{1}{2}\left(\frac{C}{C_v}\right) \quad (11)$$

These equations are identical to corresponding relations[2] obtained for Debye's theory of polar molecules.

All that this correlation means is that both theories are built upon the assumption of an exponential relaxation function whose time constant is $\alpha$. Both theories lead to variations of capacitance and loss with $\log_{10}f$ of exactly the same form and additional data is necessary to determine which (if either) of these physical pictures is applicable in any given case.

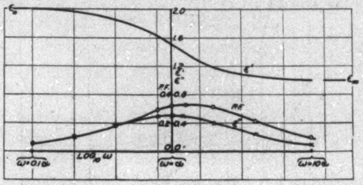

FIG. 6—DIELECTRIC CONSTANT ($\epsilon'$), LOSS FACTOR ($\epsilon''$) AND POWER FACTOR (P.F.) FOR CASE WHERE $C = C_1$ IN CIRCUIT OF FIG. 5

Contrary to the statement of Gemant,[12] we find that these two effects need not occur in widely separated frequency ranges but might occur in the same range under certain conditions. Therefore *the frequency at which the maximum loss occurs cannot be used alone as a criterion of the physical mechanism which is responsible for observed variations.*

If there is an air film between the surface of the material and the test electrodes, or if one or more layers of loss-free insulation is placed in series with the test piece, then the equivalent circuit shown in Fig. 7 may be nearer a true representation of the composite dielectric than that of Fig. 5. It can be shown[13] that these two circuits are exactly equivalent if the relations given by equations (24-32) in the appendix exist between their coefficients. Therefore such a composite insulation will also show the general characteristics of Fig. 6.

Mechanism C which can be represented by Fig. 7, also offers a possible explanation of the observed data since it is known that even with the best possible contact between the surfaces of a solid dielectric and the electrodes, polarization may occur. If a constant unidirectional potential is applied for sufficient time this back potential may become approximately equal and opposite to the applied potential.[14]

Sinjelnikoff and Walther[15] state that all the a-c losses may be accounted for by measuring the true resistance of a dielectric, taking into account this polarization potential. This, again, seems to be simply another way of looking at the Maxwell-Wagner theory.

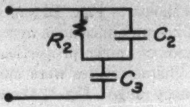

FIG. 7—SECOND FORM OF EQUIVALENT CIRCUIT FOR MECHANISM B

Whitehead[16] has shown that oil alone and oil impregnated paper both show relaxation characteristics. He studies their alternating current behavior by using a modification of Von Schweidler's[17] theory in which the relaxation function is assumed to be a sum of several exponential terms instead of a power function which was used by Von Schweidler. Assuming one term only of the exponential function, Dr. Whitehead shows curves of capacitance and loss changes with frequency exactly similar[18] to those given in Figs. 4 and 6. This again is to be expected since all three mathematical treatments start with the assumption of an exponential relaxation function. For the more general case where the relaxation function is not a simple exponential this direct correspondence no longer holds.

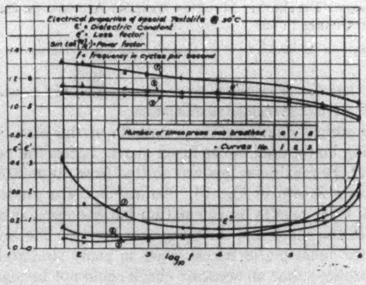

FIG. 8—CAPACITANCE AND LOSS MEASUREMENTS FOR A SPECIAL TEXTOLITE AT 30 DEG C

From the above analysis of these three mechanisms which lead to qualitatively similar results it seems that these additional conclusions may be drawn.

*a. Any mechanism causing an exponential current-time discharge curve after the removal of a constant potential, should also cause an a-c dielectric loss-frequency curve having a maximum at* $f_m = \alpha/2\pi$.

*b. Inversely, if a maximum is observed in the a-c loss-frequency curve, the exponent of the current-time curve of the same material should be given by this same relation.*

*c. Conversely, if in a given range of frequency or relaxation time, one of these effects is not found, the other should also be absent.*

## D. EXPERIMENTAL VERIFICATION OF MECHANISM B

Two types of results will now be shown which seem to verify the concept that conducting liquids (water, solvents, etc.) in small pockets throughout the volume of synthetic molded materials are responsible for the observed electrical behavior.

In Figs. 8-11 are shown the results of a series of tests to determine the effects of changing the conditions of gas evolution during the process of curing flat sheets of paper base textolite. These sheets are molded between flat steel platens and if the sheet is pressed and cooled under continuous pressure all gaseous products must either escape through the edges of the sheet by diffusion or be trapped in pockets throughout the volume of the sheet. Upon cooling, water or other vapors recondense, giving the semi-conducting pockets. Now if the press is opened several times, or allowed to "breathe" as it is called, during the curing of the sheet, it should be much easier for these vapors to escape. Therefore several samples from the same molding stock were pressed under identical pressure, temperature and time conditions, the only difference being in the number of times the press was opened or "breathed" during the curing of the sheet. In each case the sheet was cooled in the mold under pressure.

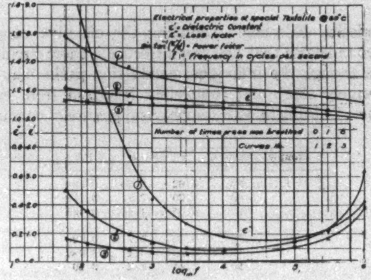

FIG. 9—CAPACITANCE AND LOSS MEASUREMENTS FOR A SPECIAL TEXTOLITE AT 60 DEG C

The capacitance and loss characteristics were then measured at three temperatures with very interesting results. In the first place, the first two conclusions drawn from the data in Table I were again verified. From the table shown in Fig. 11 taking sample No. 1 for example, the loss per unit volume increased ten fold as the temperature was increased from 30 to 90 deg C, but the power factor only increased about five fold because the effective dielectric constant had about doubled in this range.

The increase in effective capacitance with increased temperature is thought to be caused by increased conductivity and effective short circuiting of portions of the composite dielectric. Doubling the effective capacitance indicates that half the dielectric is short circuited even though the individual conducting paths may be extremely short and completely insulated from each other. This fits in with the physical picture of conducting liquids having a negative resistance-temperature coefficient in insulating cells.

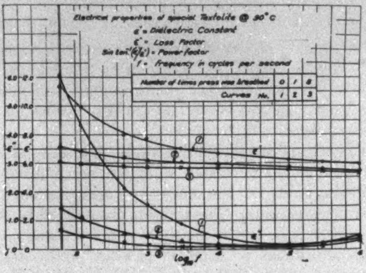

Fig. 10—Capacitance and Loss Measurements for a Special Textolite at 90 Deg C

| Sample | Temp° C | $\epsilon''$ | $\epsilon'$ | P.F. |
|---|---|---|---|---|
| 1 | 30 | 0.62 | 6.55 | 0.094 |
|  | 60 | 2.25 | 7.9 | 0.274 |
|  | 90 | 6.05 | 11.4 | 0.468 |
| 2 | 30 | 0.15 | 5.7 | 0.026 |
|  | 60 | 0.50 | 6.1 | 0.082 |
|  | 90 | 1.45 | 7.2 | 0.20 |
| 3 | 30 | 0.07 | 5.45 | 0.013 |
|  | 60 | 0.17 | 5.66 | 0.03 |
|  | 90 | 0.70 | 6.10 | 0.098 |

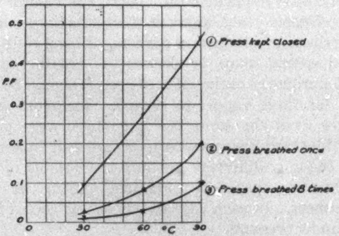

Fig. 11—60-Cycle Power Factor of Special Textolite

Showing the effect of allowing gases to escape during curing

Secondly, *these data prove that conducting liquids are a major factor in the cause of high effective capacitance and high dielectric loss in molded materials.*

Thirdly, *the data indicate that in molded materials conducting liquids are held within small pockets, or if they are absorbed on the surface of the paper fibers according to the physical picture of Murphy and Lowry,*[11] *these conducting paths must be insulated from each other.*

That the former would give quantitatively similar results we have attempted to show by building artificial imperfect dielectrics from known components. The first attempt is shown in Figs. 12 and 13. Small fused quartz tubes of known dimensions were filled with semi-conducting liquids of known properties and the capacitance and loss characteristics were measured over the available frequency range. Fig. 12 shows that the maximum in the loss curve may occur at very low frequencies and that wherever both the $\epsilon'$ and $\epsilon''$ curves are rising with decreasing frequency, some form of relaxation is probably responsible. These curves are strikingly similar to those shown in Figs. 2, 3, 8, 9 and 10 and indicate that *the Maxwell-Wagner theory probably accounts for all the data presented in this paper.*

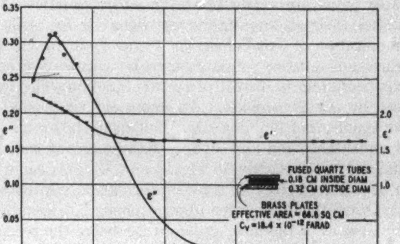

Fig. 12—Capacitance and Loss Measurements for an Imperfect Dielectric Made by Sealing Alcohol in Small Fused Quartz Tubes

Constants for the alcohol are $\epsilon' = 4.62$ and $\rho = 1.7 \times 10^{10}$ ohms per cm cube

By simply changing the constants of the semi-conducting liquid used in the fused quartz tubes, the position of the maximum loss was shifted from 30 to 20,000 cps, as is shown in Fig. 13. An attempt was made to check these results by calculation but the circular section of the tubes and the air spaces between the tubes and the brass plates necessitated so many simplifying assumptions that an accurate check could not be made.

Therefore the same two liquids were used in a double-walled glass cell of better geometric design and the measurements repeated as shown in Figs. 14 and 15. Here again the same characteristic functions were obtained and with the simpler geometric design they can be checked very closely by calculation. For example, let us determine the critical values for Fig. 15. The dimensions of the cell are shown. The characteristics of the semi-conducting liquid are shown in Fig. 16. The dielectric constant measurements of this liquid were very uniform but the measurements of equivalent parallel conductance were quite difficult especially at radio frequencies because of high losses. However the results could best be interpreted as a constant value of conductance independent of frequency, as is shown on the curve sheet.

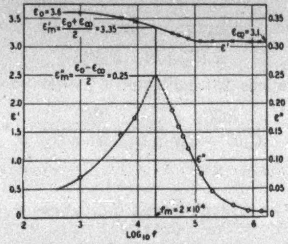

FIG. 13—CAPACITANCE AND LOSS MEASUREMENTS FOR AN IMPERFECT DIELECTRIC MADE BY SEALING AN ALCOHOL IN SMALL FUSED QUARTZ TUBES

Constants for the alcohol are $\epsilon' = 16.0$, $\rho = 7.02 \times 10^6$ ohms per cm cube

From the dimensions of the cell we calculate

$$C_v = 0.0884 \times 10^{-12}\,\frac{219.8}{0.4} = 48.6 \times 10^{-12} \text{ farad} \quad (12)$$

$$C_{empty\ cell} = 0.0884 \times 10^{-12}\,\frac{219.8}{\frac{0.2}{1}+\frac{0.2}{5}}$$

$$= 81 \times 10^{-12} \text{ farad} \qquad (13)$$

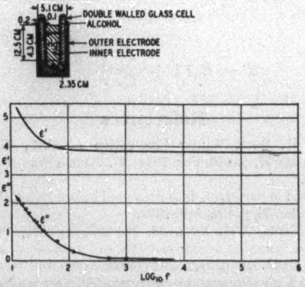

FIG. 14—CAPACITANCE AND LOSS MEASUREMENTS FOR AN IMPERFECT DIELECTRIC MADE BY SEALING AN ALCOHOL IN A DOUBLE WALLED GLASS CELL

Constants for the alcohol are $\epsilon' = 4.62$, $\rho = 1.7 \times 10^{10}$ ohms per cm cube

in which the dielectric constant for the glass is assumed to be 5. The actual measured capacitance of the empty cell was found to be $80 \times 10^{-12}$ farads, so the calculated effective area was corrected to 217 instead of 219.8 sq cm.

Now the equivalent circuit for this combination is represented by Fig. 7, since the glass is assumed to be loss free and the liquid has both conductance and capacitance. Therefore we have

$$C_3 = 0.0884 \times 10^{-12}\left[\frac{5 \times 217}{0.2}\right] = 480 \times 10^{-12} \text{ farad} \quad (14)$$

$$C_2 = 0.0884 \times 10^{-12}\left[\frac{16 \times 217}{0.2}\right]$$

$$= 1{,}530 \times 10^{-12} \text{ farad} \qquad (15)$$

$$R_2 = 7.02 \times 10^6\left(\frac{0.2}{217}\right) = 6.47 \times 10^3 \text{ ohms} \qquad (16)$$

Now converting these to equivalent coefficients in Fig. 5 by using equations (**30-32**) we have

$$C = 114.5 \times 10^{-12} \text{ farad} \qquad (17)$$

$$C_1 = 366 \times 10^{-12} \text{ farad} \qquad (18)$$

$$R = 11.3 \times 10^4 \text{ ohms} \qquad (19)$$

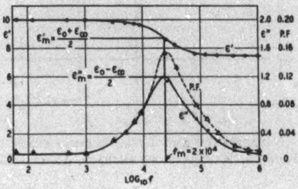

FIG. 15—CAPACITANCE AND LOSS MEASUREMENTS FOR AN IMPERFECT DIELECTRIC MADE BY SEALING AN ALCOHOL IN A DOUBLE WALLED GLASS CELL

Constants for the alcohol are $\epsilon' = 16.0$, $\rho = 7.02 \times 10^6$ ohms per cm cube

Then from equations (**9**), (**10**) and (**11**) the characteristic coefficients for this composite dielectric may be determined. These calculated values are tabulated below for comparison with the experimentally determined data.

TABLE II—COMPARISON BETWEEN CALCULATED AND OBSERVED VALUES FOR FIG. 15

| | $f_m$ | $\epsilon_0$ | $\epsilon_\infty$ | $\epsilon_m''$ |
|---|---|---|---|---|
| Calculated | $1.23 \times 10^4$ | 9.89 | 7.53 | 1.18 |
| Observed | $2.0 \times 10^4$ | 10.0 | 7.4 | 1.2 |

*The close agreement proves the applicability of the theory in determining capacitance and loss characteristics of such a composite dielectric.*

The author is happy to acknowledge his indebtedness to his coworkers, particularly S. I. Reynolds of the General Engineering Laboratory, for assistance in making the measurements reported in this paper.

## E. CONCLUSIONS

1. In composite dielectrics, capacitance and loss measurements taken at one frequency and temperature

cannot be used to predict characteristics at other frequencies and temperatures except under special conditions where the type of variation to be expected is already known.

2. When $\epsilon'$ is not constant, or the loss angle is large, changes in power factor are not accurate measures of changes in dielectric loss but changes in $\epsilon''$ truly represent such changes measured as watts loss per cycle per unit volume per (unit potential gradient)$^2$.

3. The frequency $f_m$ at which maximum loss occurs cannot be used alone as a criterion of the physical mechanism which is responsible for observed variations since under certain conditions the different mechanisms may possibly cause changes in characteristics in the same frequency range.

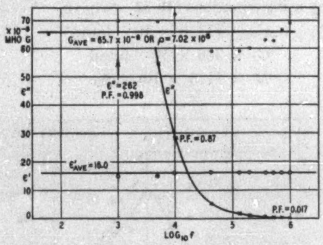

FIG. 16—CAPACITANCE AND LOSS MEASUREMENTS FOR THE ALCOHOL REFERRED TO IN FIGS. 13 AND 15

4. Some form of the Maxwell-Wagner theory of imperfect dielectrics is the most probable explanation of data on molded materials presented in this paper.

## Appendix

### RELATIONS BETWEEN COEFFICIENTS TO MAKE IDENTICAL THE CIRCUITS SHOWN IN FIGS. 5 AND 7

For a simple circuit composed of $R_p$ and $C_p$ in parallel, the complex expression for the admittance is

$$Y = \frac{1}{R_p} + iwC_p = \frac{1 + pR_pC_p}{R_p} \qquad (20)$$

Also for the simple circuit composed of $R_s$ and $C_s$ in series we have the impedance.

$$Z = R_s + \frac{1}{iwC_s} = \frac{1 + pR_sC_s}{pC_s} \qquad (21)$$

In the second form of each of these expressions the operator $(p)$ has been substituted for $(iw)$.

In a similar way the circuits shown in Figs. 5 and 7 are represented by equations (22) and (23) respectively.

$$Y = \frac{1}{\dfrac{1}{pC_3} + \dfrac{R_2}{1 + pR_2C_2}} = \frac{pC_3 + p^2R_2C_2C_3}{1 + pR_2(C_2 + C_3)} \qquad (22)$$

$$Y = pC_1 + \frac{pC}{1 + pRC} = \frac{p(C + C_1) + p^2RCC_1}{1 + pRC} \qquad (23)$$

By the operational calculus, the condition under which these last two equations are identical is that corresponding coefficients of $(p)$ must be equal. Therefore we have:

$$C_3 = C + C_1 \qquad (24)$$

$$R_2C_2C_3 = RCC_1 \qquad (25)$$

and

$$R_2(C_2 + C_3) = RC \qquad (26)$$

From equations (25) and (26):

$$R_2 = \frac{RCC_1}{C_2(C + C_1)} = \frac{RC}{C_2 + (C + C_1)} \qquad (27)$$

from which

$$C_2 = \frac{C_1}{C}(C + C_1) \qquad (28)$$

and substituting back in equation (26) we have

$$R_2 = R\left(\frac{C}{C + C_1}\right)^2 \qquad (29)$$

Equations (24), (28) and (29) give the coefficients of Fig. 7 in terms of those of Fig. 5 to make the two circuits electrically equivalent.

Again, if the coefficients of Fig. 7 are known, those which will make Fig. 5 electrically equivalent may also be derived from the above equations and are as follows:

$$C = \frac{C_3^2}{C_2 + C_3} \qquad (30)$$

$$C_1 = \frac{C_2C_3}{C_2 + C_3} \qquad (31)$$

$$R = R_2\left(1 + \frac{C_2}{C_3}\right)^2 \qquad (32)$$

# Discussion

## THE DIELECTRIC LOSSES IN IMPREGNATED PAPER

(WHITEHEAD)

## CAPACITANCE AND LOSS VARIATIONS WITH FREQUENCY AND TEMPERATURE IN COMPOSITE INSULATION

(RACE)

**A. A. Bolsterli:** Of the many valuable results of Doctor Whitehead's new series of researches I wish to single out those given under the heading *Dielectric Constant.* This subject, no less than the others dealt with in the paper, is of great interest not only to the cable engineer, but to the designer of static condensers as well.

Considering the far from simple structure of paper as a conglomeration of fibers, it is remarkable that the system paper-air or paper-oil should resolve itself, as far as dielectric constant is concerned, into a simple two-layer dielectric. Evidently the author starts with this assumption using it for the determination of $(K_p)$ and $(m)$. The correctness of the values of $(K_p)$ and $(m)$ as determined from test data rests therefore upon the degree to which the aforementioned assumption holds true. While there is no question in my mind that the author's assumption is very well founded, it would be interesting to know whether any other checks were made to verify it. I have in mind the determination of $(m)$ from mechanical data. If $(S)$ is the specific gravity of the dry paper, $(S_p)$ that of the solid paper fiber, the volume ratio paper: air is given by:

$$m = \frac{S}{S_p - S} \tag{1}$$

*The International Critical Tables* (Vol. II, p. 237) give the specific gravities of fibers determined in benzene after Vignon as follows:

| | |
|---|---|
| Cotton | 1.50 to 1.55 |
| Linen | 1.50 |
| Hemp | 1.48 |
| Jute | 1.48 |

No value is given for cellulose fibers prepared from wood which make up Kraft paper. Taking the author's values of $S = 1$ and $m = 2.82$ (Table IV, for 30 deg C) and applying the aforementioned formula (1), the specific gravity of paper fiber is found to be $S_p = 1.354$, which value differs appreciably from the above figures for related fibers. Probably the difference can be ascribed, at least in part, to moisture content, the author's figures referring to highly dried paper, whereas nothing is known as to the condition of the fibers to which the other figures refer.

If a test specimen is built up in the shape of a plane-layer condenser with a number of sheets of paper as the dielectric, it is possible to vary the volume ratio paper-air or paper-oil, that is to say the author's $(m)$, by compressing the condenser in a hydraulic press. If $(n)$ denotes, the percentage compression, *i.e.*, the reduction in layer thickness referred to the thickness uncompressed, of the layer, the volume ratio $(m)$ for dry paper at compression $(n)$ is:

$$m = \frac{S}{S_p(1-n) - S} \tag{2}$$

where $(S)$ is the specific gravity of the layer uncompressed and $(S_p)$ that of the solid paper fiber assumed to be incompressible. Substituting the values obtained by (2) in the author's formula (1), the dielectric constant can be calculated for any degree of compression. Since the corresponding capacity measurements of the condenser furnish the measured dielectric constant, an accurate check of the two-layer hypothesis would seem to be possible by this method, which by way of extension is applicable to impregnated paper as well.

Fig. 1 of this discussion shows the data obtained on a test condenser made up of 200 layers of 5 sheets each of 0.75-mil Kraft paper. For the calculated curve the values $K_p = 5.45$ and $S_p = 1.354$ from the author's paper were used. In spite of the fact that these values are in all probability only approximately true for the paper we used, the agreement between calculated and measured values is fair, as is seen from the curves.

Mechanical compression, while scarcely a factor in cable design, is a well known means of controlling dielectric constant in paper condensers, whether they are of the compressed-gas dry type or the impregnated type. The method indicated above would seem to afford an extension of Doctor Whitehead's method of predetermining the dielectric constant to include the feature of compression.

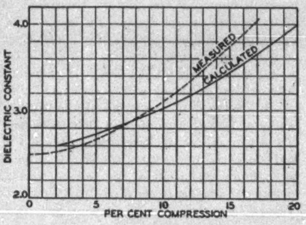

FIG. 1—DIELECTRIC CONSTANT OF DRY PAPER DIELECTRIC IN FUNCTION OF MECHANICAL COMPRESSION

Dielectric layer consisting of 5 sheets of ¾ mil condenser tissue (calendered Kraft) thoroughly dried, under heat and vacuum before test. For the measured values, compression is referred to thickness under 50 lb per sq in. compression

**W. A. Del Mar:** The research work done by the cable manufacturers necessarily is directed toward immediate commercial ends. Hence, while a vast amount of information is unearthed in the manufacturers' laboratories, in the course of solving practical problems, there is little opportunity to organize it into presentable form, once the practical problems are out of the way.

In these papers which record researches under the auspices of the various groups interested in cable engineering, the manufacturer's engineer encounters a great deal of familiar material and is pleased to see it organized into a form where it is a permanent record. Doctor Whitehead has gone through the experience of seeing a simple problem expand and unfold into seemingly endless new problems, with no end in sight. It is, therefore, a cause of genuine regret that we find Doctor Whitehead stating that this work must cease for lack of financial support.

Cable manufacturers have discovered that oil suppliers are particularly ignorant of the properties of their oils as related to their performance in cables. Transformer manufacturers found that it required considerable effort on their part to interest oil refiners in sludge prevention, but several of them are now active in that field. No such activity exists with regard to cable oils. It would be greatly to the advantage of the oil refiners if they would take advantage of Doctor Whitehead's fine ability, experience, organization and equipment, to educate them about their cable oils and enable them to sell their product intelligently to the cable manufacturers.

Doctors Whitehead and Race appear to differ somewhat in their views of the bearing of their respective experimental data on the Maxwell theory of absorption in composite dielectrics. It would be interesting to have the two authors explain the reasons for their views in greater detail.

**Hubert H. Race:** Referring to the sentence in which Doctor Whitehead states that "In particular, in the case of insulating oils and cellulose paper, each of these materials is so complex in its dielectric properties that, to the experimenter, it is almost immediately obvious that a quantitative agreement with any theory of dielectric loss cannot be expected from the studies of the behavior of the paper when impregnated with the oil," it seems that this comment may be made. Such a statement should not be discouraging to the investigator but rather it should challenge him to try to determine the physical reasons underlying these complexities. The characteristics of a dielectric are anomalous only so long as they remain unexplained and it seems that the greatest value to be gained from insulation research will come from increased understanding of the causes of such characteristics.

Naming experimentally determined characteristics, of which dielectric absorption is a good example, is of little value unless they can then be studied sufficiently to obtain a physical understanding of their causes. For example, if it can be shown that the losses in oil impregnated paper are definitely dependent upon current conduction in minute restricted paths within cellulose fibers or in absorbed conducting films along the surfaces of cellulose fibers then such measurements can serve as definite guide posts in changing the factory treatment of paper and oil so as to decrease these conduction losses. Or again, if it can be shown that conduction plays only a minor part and that adhesive or polar orientation forces in cellulose-oil-water interfaces are mainly responsible for the observed phenomena, then an entirely different line of attack will be necessary in order to reduce these losses. Some data presented at the November meeting of the National Research Council in Baltimore (see p. 53 of the report of the Committee on Electrical Insulation of the Div. of Engg. and Industrial Research of the N.R.C., Dec. 1932) may be taken as a slight indication of the second mechanism as a possible factor contributing to the dielectric loss of oil impregnated paper.

Recalling a few steps in vacuum tube development will indicate the point of this comment. Little progress was made so long as "current leakage" was known only as an unexplained, externally measured property of incandescent lamps. The development of the many forms of vacuum tubes now in use was made possible only because the physical mechanisms and governing laws of phenomena such as electron emission and space charge formation were minutely studied and thoroughly understood. Correspondingly, intensive studies of the properties of dielectrics may lead to important improvements in insulating materials.

In discussing changes in dielectric constant of oil with oxidation, Doctor Whitehead stresses the non-uniform distribution of charged particles as the possible cause but neglects to mention polar orientation. In *Physics*, May 1932, W. N. Stoops of the Westinghouse Elec. and Mfg. Co. published a paper showing increases in dielectric constant with oxidation of commercial oils, which he interprets as resulting from increases in polar constituents. In the *Journal of Physical Chemistry*, July 1932, I published a paper showing that increases in high frequency losses are caused by polar particles because the hydrophil content increased with oxidation in direct proportion to the dielectric losses. I also found that a portion of the loss remained even when the hydrophil content was extrapolated to zero indicating that two mechanisms, namely the orientation of polar particles and the migration of charged particles may simultaneously be contributing toward the capacitance and loss characteristics of an insulating liquid.

In my present paper it is shown that several different mechanisms may lead to similar electrical characteristics and I should like to add that work on high loss materials such as synthetic resins may be directly applicable to oil impregnated paper even though the resultant losses in the latter are of a much smaller order of magnitude. Considerable additional work should certainly be done to obtain more information on the mechanism of dielectric loss and associated phenomena in composite insulation since losses generate heat and most failures which do not result from mechanical trouble are probably pyroelectric.

**J. B. Whitehead:** Doctor Race gives us some interesting data on a class of insulating materials which are not often discussed, namely those having very high values of dielectric loss. We note values of power factor up to 40 and 50 per cent which thus approach the values frequently observed in electromagnetic machinery.

Doctor Race has pointed out the value of the "loss factor" rather than the "power factor" for describing insulation of this class. He makes out a very good case. On the other hand, I doubt whether it would be advantageous to employ the loss factor for the high grade insulation which is necessary for high voltage equipment, as for example, impregnated paper cables. In this class, the loss per cu-cm often is so small that the values of the loss factor would become decimals of small magnitude, involving the use of negative exponents of 10. Moreover, capacitance changes with both frequency and temperature are small in this class of insulation, and there is no difficulty in passing immediately from values of power factor or phase difference to those of loss. It seems to me, therefore, that there would be no advantage in using the loss factor in discussions of insulation of this class.

The paper also presents examples of the now well known maxima of power factor with corresponding capacitance changes for complex insulation over sufficiently wide ranges of either frequency or temperature. This type of variation has been recognized by students of dielectric theory ever since the first extension of Maxwell's theory of the layer dielectric to the alternating case. Emphasis has recently been given to a similar type of variation involved in Debye's theory of polar molecular orientation. The fact that each of these phenomena has associated with it a dielectric relaxation function, also is well known. Doctor Race emphasizes again this convenient criterion for the presence of the types of loss and capacitance variations under discussion.

To the several physical pictures which Doctor Race is suggesting for aiding our thought of these matters, I would suggest that he might add that of the motion of ions of various sizes in the liquid portions of his dielectrics. As to his conclusion No. 3, that molecular orientation and dielectric absorption may occur in the same frequency range, the vital question here is whether molecules will oscillate and relatively large ions vibrate in the same frequency range of alternating stress. My own feeling is that they are not likely to do so and that changes in capacitance and power factor in commercial materials and in the lower ranges of frequency are due to the various manifestations of anomalous conduction and dielectric absorption, rather than to molecular orientation.

**R. J. Wiseman:** Doctor Whitehead's paper is an addition to several papers by him on the dielectric losses in impregnated paper which try to show us where these losses come from, some of the influencing factors and what kind or kinds of oil are best suited to obtain the highest efficiency in cable operation. This last paper tends to indicate that the so-called oil-filled type of cable is, in the last analysis, the only true one. Theoretically, this is true. Practically and economically it is not necessarily so. We have had and still have very good operation on the solid type of cable up to and including 66 kv. One must not be led to assume that by using special highly refined oils, we are going to eliminate cable failures.

Doctor Whitehead refers to power factor of the dielectric in high voltage cables and in impregnated paper condensers within the range of 0.001 to 0.003. I have yet to see either in oil-filled cable or solid type cable, a power factor of 0.001. We do get about 0.003 in the beginning, but with time, this will increase. We cannot assume, even though we would like to, that it will stay around 0.003. It is true, as Doctor Whitehead states, that under most conditions, the losses in the dielectric for all voltages are small, as compared with those in the conductor and so do not seriously limit the current carrying capacity of the cable.

We prefer not to lead the user to believe that they are not going to change nor do we want him to think they are going to increase to a dangerous value. Actually, today, the types of oils that are used are practically quite stable and the user need have no fear of them. The problem confronting the cable user today is not so much the stability of the dielectric, but the lead sheath. For the past ten years we have been urged to improve our oil and paper, lower moisture content, lower void volume, which means in turn, higher oil content. All these were necessary and have been accomplished, but we still get cable failures. An analysis of these failures indicates many due to the lead sheath. We assign the cause as defective lead and we give the manufacturer of the cable a black mark.

About two and one-half years ago the company the writer is associated with started studies on the influencing factors of good cable operation. Elaborate researches have been conducted by simulating operating conditions with overvoltage tests. As a part of this study we watched the change in power factor, hot spot temperatures, internal pressures and sheath expansion. We have had cases of practically no change in power factor up to the time of failure and again a rapidly increasing power factor, but a long time to failure; we have noted hot spots at which failure has occurred and a few cases away from a hot spot; internal pressures at the conductor have been as high as 115 lb per sq. in. and at the sheath 80 to 85 lb per sq in.; permanent expansion of the sheath and again moderate elasticity. Examination of the cable after failure has indicated migration of the oil from the conductor to the sheath, leaving dry zones in which ionization has and yet has not occurred. The most startling of all were the very high internal pressures developed. We immediately associated these with the lead sheaths and studied what influence they would have. Samples of lead sheath were subjected to constant internal pressures of 40 lb per sq in. at room temperature, 40 deg C and 53 deg C. The sheaths at 53 deg C expanded quite rapidly and burst, those at 40 deg C also showed a definite expansion and with time, burst; those at room temperature expanded, but did not burst.

Calculation of the hoop stresses in the lead showed a tensile strength over that permissible, according to recent studies such as those by Professor Moore of the University of Illinois, for the lead to stand if it is not to stretch. Here is a clue to the failure of cable and where we have assigned the cause of failure to manufacture, actually, it is an operating cause resulting from internal pressures which the lead physically cannot withstand. In improving our dielectric we have forgotten the protecting sheath. We have not changed our tables of lead sheath thicknesses ever since they were originally gotten up, which was on a rule of thumb basis. Only recently has it become serious and our next step in improved quality of cable and, therefore, cable operation, is to face the facts and increase our lead walls, particularly for cables over 2.5 in. in diameter. A 1/64 in. increase will greatly help, but we should go further and base the thickness for these large diameter cables on a maximum hoop stress of about 180 lb per sq in. for a constant internal pressure of 20 lb per sq in. Unless we do, we are not going to reduce materially the record of cable failures. The increase in cost of cable is moderate, far less than the cost of replacement of a section which has failed. This subject equally is as important to all of us as further improvement in the dielectric.

**J. B. Whitehead:** The importance of fundamental physical and chemical research into the properties of dielectrics cannot be emphasized too often.

Doctor Race has criticized more than once my use of the term "dielectric absorption" for describing the well known phenomenon of residual charge in complex dielectrics. Whether or not we understand completely all of the phenomena leading to residual charge, there obviously is a practical advantage in having a brief term for the convenient description of the phenomenon. Moreover, the use of such a brief term should not, and probably never does, imply indifference to the importance of the study of underlying causes. But beyond this, there are other even better grounds warranting the use of the term. It has been used by distinguished students of dielectrics, reaching back to the time of Maxwell, for the description of the important phenomenon of residual charge, and for which he has given us his classical theory. Let it be remembered that when two dielectrics having different values of conductivity and dielectric constant, are mixed, we shall have the phenomenon of residual charge or dielectric absorption. It may be that the conductivities and dielectric constants are complex as caused by ionic adsorption, space charge, molecular orientation, or other cause. The basis phenomenon will always remain. Perhaps Doctor Race will suggest a better term for convenient reference to this by far the most important cause of dielectric loss at low frequencies.

Doctor Wiseman raises the question as to the relation of our results to the performance of commercial cables. While the improvement of the latter is always the ultimate object of our work, I take it that the first principle of all basic research is the uncovering of new knowledge and facts. Thus, the point of view in our research has been a determinatoin of the ultimate available properties of impregnated paper, the explanation of these properties, and the laws which govern them. It may be that at the present moment, our results only constitute a remote target which it may be impossible to hit, or even reach, from the standpoint of present commercial economics and practise. On the other hand, the visibility of the target will be a stimulus for the development of new means of reaching it, and a proof of the value of additional expenditures to that end. In short, the value of spending more money to get better cables.

We have in this work however, approached very closely the conditions of practise in the oil-filled cable. I believe that our results may be used with great reliability in any comparative study of the relative values of different oils for that type of cable. Doctor Wiseman admits this, but calls attention to limitations of a quite different sort, which are inherent in the solid type of cable. Our work has not attacked the great problems of sheath expansion, and gaseous ionization as a result of temperature cycles, in the solid cable. It may be pointed out here, however, that when under progressive development, the oil-filled principle becomes more general and when, if ever, the solid cable, through increasing sheath thickness or by other means, ever reaches the stage where it is free from internal voids, engineers will then turn to the basic researches of ourselves and others who are endeavoring to formulate the underlying properties and laws of the materials, as the only limitations to performance in practise.

**H. H. Race.** Professor Whitehead has apparently misinterpreted my comment regarding the use of the term "dielectric absorption." The report on "Proposed American Standard Definitions of Electrical Terms" defines dielectric absorption "that property of an imperfect dielectric whereby there is an accumulation of electric charges within the body of the material when it is placed in an electric field." This then is an externally measured property of a composite dielectric as a whole and carries with it no necessary explanation of the physical causes of its origin. I do not object to the use of the term dielectric absorption nor have I any other name to offer, but I should like to emphasize again the need for studying more intensively the underlying physical phenomena so that for representative dielectrics answers may be obtained to questions such as the following:

1. What is the source and size of ions?
2. How far and how fast do they move?
3. Do they accumulate to form space charges at the electrodes or is the displacement uniform throughout the material?
4. How can the formation of ions be prevented?
5. What part is played by orientation of polar molecules in a viscous liquid medium?
6. What part is played by films of polar liquids adsorbed on cellulose fibers in oil impregnated paper?

# A New Method for Initiating the Cathode Of An Arc

BY J. SLEPIAN*
Fellow, A.I.E.E.
and
L. R. LUDWIG*
Associate, A.I.E.E.

## I. INTRODUCTION

THE specific form of electrical discharge in gases which we know as the electric arc is a most essential and useful element in many types of engineering apparatus and in many applications. Its utility in arc lamps, arc rectifiers, arc welders, lightning arresters spark gaps is obvious. Where the arc is useful, it owes its utility to its ability to carry large currents at a low voltage to a degree incomparably greater than that of other forms of discharge such as glows, Townsend discharges, cathode rays, positive ion currents, etc.

The origin or seat of this great capacity to carry large current at low voltage which is enjoyed by the arc resides quite definitely at the cathode, where with a drop of only ten or twenty volts, thousands of amperes per cm$^2$ are carried. In fact it is only at the cathode that the arc differs essentially from the glow for which the cathode drop is usually several hundred volts, and the current density even at atmospheric pressure is only about ten amperes per cm.[2] The problem of the formation of an arc, as distinguished from other types of discharges, then reduces to a study of the cathode of an arc, and the circumstances which cause an arc cathode rather than a glow cathode to form.

## II. THEORIES OF CATHODE OF AN ARC

Since gases are normally insulating, the maintaining of a discharge requires the presence of ionizing agents. In the gas itself, ionization by collision with molecules of electrons accelerated by the electric field, seems to be adequate to account for the observed conductivities, at least at low gas pressures. At high gas pressures, of the order of atmospheric, thermal ionization of the gas seems to play a part,[1] and it has been found that high enough temperatures are observed[2] to produce thermal ionization.

At the cathode a space charge sheath exists and the whole current must be carried either by electrons liberated from the cathode or by positive ions from the gas. If the current density is very small, the latter alternative is sufficient and is probably the mechanism of the Townsend or dark discharge occurring at high gradients, just below the sparking potential for the electrode configuration in the gas. The ionization of the gas near the cathode is produced principally by ionization by collision with gas molecules or positive ions.

As the current density in the Townsend discharge is increased, the space charge of positive ions near the cathode causes an increase in the gradient there, and finally electrons are set free from the cathode by impact of positive ions or excited atoms. The essential character of the discharge is not changed, however, and the setting free of electrons from the cathode by such impacts may well be included in the general term ionization by collision. If there is no other source of ionization than ionization by collision as thus generalized, increase in current density will change the Townsend discharge continuously into the glow with a minimum drop at the cathode of several hundred volts, and with a current density, at this minimum, of about ten amperes per cm$^2$ at atmospheric pressure, and varying as the square of the pressure. Increasing the current density above this figure raises the cathode drop.

Ionization by collision alone then can account only for low current density discharges requiring at least hundreds of volts. For an arc cathode to occur, some new ionizing agent must make its appearance. The search for what this new ionizing agent may be forms an interesting chapter in electrophysics.

The first theory was that thermionic emission at the cathode is this new ionizing agent.[3] In most types of arcs the cathode is at a high temperature, and for some arcs, certainly at a temperature high enough for sufficient thermionic emission. However, it is certain that steady arcs do exist with cathodes which are too cold for thermionic emission,[4] and that arcs are formed from glows in times which are too short for the cathode to heat up.[5] Other ionizing agents are necessary for these non-thermionic arcs. Note, however, that for these thermionic arcs a considerable energy input is necessary to bring the cathode up to the necessary temperature so that such an arc cannot be formed from a glow in a short time.

Another theory, and one which is widely accepted, is that in the arc, a very high positive ion space charge density adjacent to the cathode produces so intense an electric field there that electrons in sufficient number are pulled out from the cathode.[6] To form so intense a space charge, however, calls for a current density of several thousand amperes per sq cm[7] so that according to this theory such current densities are necessary before an arc cathode can be formed.

Still another theory is that very intense thermal ionization in the gas layer immediately adjacent to the cathode supplies sufficient positive ions to carry the current to the cathode.[8] Here again, because of the large heat loss from this hot gas layer to the cold cathode, a considerable current density is necessary.

We see that according to all these theories a considerable energy input density or current density at the cathode is a prerequisite for the formation of an arc cathode.

## III. METHODS FOR INITIATION OF AN ARC CATHODE

The problem with which the authors have been concerned, and whose solution forms the subject of this paper was the frequent repeated initiation of an arc cathode upon a cold electrode within a very short and precisely placed time interval, less than a thousandth of a second, and in gases at low pressures. It is well to consider the known methods of arc cathode initiation to see how closely they come to meeting the requirements of this problem.

*1. The Thermionic Cathode.* The method of using a cathode with a separate source of energy to bring it up to a temperature sufficient for thermionic emission is regularly used in hot "filament" gas-filled tubes. However, if the "filament" is to be of reasonable size, and the separate source of energy not excessively large, the filament cannot be brought up to the necessary temperature in the required small time.

*2. Separating Contacts.* When metallic contacts are separated in circuits carrying an ampere or more, an arc is formed at once. Several theories have been advanced as to the way in which the arc cathode is formed there. These theories depend upon the great concentration of the current and intensification of the electric field at the last contact point of the separating electrodes.[9,10]

Although this method is widely used in switches, arc lamps, welders, and for starting of mercury arc rectifiers, the mechanical inertia of the separating contacts makes this method impractical for solving the problem set by the authors.

*3. The Blowing Fuse.* Closely related to the method of separating contacts is the blowing of a fuse wire.

By using a fine wire or film, the quick and accurate starting of the arc can be accomplished. The requirement of quick and frequent repetition of the starting operation, however, introduces difficulties. One possibility is the quick formation and re-formation of a conducting film upon an insulating surface by condensation from a metal vapor, and the authors have had some success in this way, but the method which is described later in this paper is believed to be better.

*4. Spontaneous Transition from Glow to Arc.* A glow between electrodes may be readily and quickly started by the application of sufficient voltage. In many circumstances the glow cathode will change spontaneously into an arc cathode. For example, if the energy density at the cathode is large enough, the cathode will heat up, and may reach a temperature for sufficient thermionic emission to permit the change to an arc cathode. But at low gas pressures, since the glow current density is very low, such heating cannot occur, and at high gas pressures, the heating is still too slow to solve the problem of the rapid and repeated initiation of the arc cathode required by the authors.

Nevertheless, sudden and rapid transitions to the arc form of cathode do occur in actual glows even at low gas pressures. The causes of such transitions are not well understood, and the prevention of such occurrences is the fundamental problem of mercury arc rectifiers and similar devices.

Researches of the authors[11] and others[12] indicate that these causes are spontaneous and randomly occurring agents lasting individually for only some few millionths of a second, and which somehow cause a sufficiently high current density to appear at some point of the cathode for maintaining an arc cathode. The average frequency of occurrence of such causes varies in a direct manner with the current density and voltage of the glow. At low gas pressures, where the glow current density is very small, the average frequency of occurrence of these causes is too small for the solution of the authors' problem to be found in this way. Only at high pressures, about atmospheric, is the frequency of occurrence of these causes great enough to give certainty that an arc cathode will form within a few thousandths of a second.[5]

*5. The Electric Spark.* This method deserves a special place because it deals with a transient form of glow cathode which is particularly effective in initiating an arc cathode at high gas pressures. The spark is initiated by high voltage breakdown between spaced electrodes, and since the only ionizing agent at the cathode is ionization by collision, we must describe the cathode condition as a glow. The characterizing feature of the spark is the very rapid growth of the current sent through the discharge. Since the glow cathode which initially covers only a small area spreads rather slowly,[13] a very high current density may be built up momentarily in the glow cathode. If a sufficiently high current density may be reached in the glow the frequency of occurrence of spontaneous transition causes becomes sufficiently great to insure the prompt initiation of an arc cathode.

At low gas pressures, even with high applied voltages from sources capable of giving a rapid rate of increase of current, the current density in the glow cathode remains low and an arc is not struck. Generally, one would say that a "spark" does not form at low gas pressures.

[13] Steenbeck, *Arch. f. Elek.*, **26**, 306, 1932.

*6. The High Frequency Discharge.* This method is closely related to the methods described in *4* and *5*. A discharge is started between spaced electrodes by application of sufficient voltage of high frequency. Again, since the only ionizing agent is ionization by collision, condition at the momentary cathode must be described as a glow. However, in the high-frequency glow the current density may be very large compared to that at the cathode of a steady or low-frequency glow. In the steady glow the current density at the cathode is limited by the space charge of the positive ions. But in the high-frequency glow such space charges do not have time to form. Thus high-density positive ion currents will flow in alternate half cycles and with such high current density the frequency of occurrence of spontaneous glow to arc transitions will be very great.

The method of the high-frequency discharge appears to be practical according to the experience of the authors, but they believe the new method to be described in this paper is better.

*7. Striking a New Cathode from an Already Existing Arc.* Conditions at an electrode made negative to an existing discharge are essentially the same as those at the cathode of a self-maintaining glow, except that the positive ion currents may be drawn at a voltage in itself too low for the maintenance of a glow. To insure the prompt striking of an arc cathode at such an electrode, the methods already described as effective for the glow may be used.

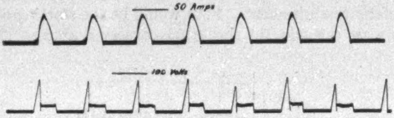

FIG. 1—OSCILLOGRAM SHOWING INSTANTANEOUS VOLTAGE AND CURRENT OF IGNITING ELECTRODE

However, in this case, an additional possibility exists. The density of ionization of the already existing discharge may be raised to so high a value adjacent to the electrode that even with low applied voltage, the positive ion current density will be so large that there will be prompt occurrence of a cause for transition to an arc cathode. This is the method used in the Deion circuit breaker[14] for striking new cathodes on the many plates in the deionizing chamber. The arc which is first drawn at separating contacts is driven by a magnetic field up into slots in the plates, where the reduction of arc section so increases the density of ionization that arc cathodes at once form on the plates.

The authors have also successfully applied this method to the striking of an arc cathode to a mercury electrode in an evacuated vessel. An arc from a separately heated thermionic filament cathode was started, but it was compelled to take a constricted path close to the mercury, thus causing the density of ionization to be very high there. A small voltage difference between the mercury and the discharge would cause the prompt formation of an arc cathode on the mercury.

## IV. THE LIGHT CONTACT ARC STARTER

A form of arc cathode starter of the separating contact type devised by the authors deserves special mention, because to a considerable degree it was free from the inertia difficulty of ordinary separating contacts. A small section pointed tungsten rod was placed in a mercury arc tube so that it dipped slightly to a depth of about one millimeter below the mercury surface. On sending sufficient current through the rod, the cathode of an arc was promptly started at the rod-mercury junction, and this starting could be regularly repeated sixty times per second. The explanation is believed to be as follows:

The current through the rod heated the rod-mercury junction, but the temperature had only to rise to that at which mercury has a vapor pressure of one millimeter, that is, about 125 deg C when a film of vapor would form around the rod, separating it from the rod, and starting an arc cathode on the mercury. In the particular tube used, when such an arc cathode started, the current was diverted to another anode and the arc cathode moved on the mercury surface away from the rod junction. With the current diverted from the rod, the film of vapor around the rod point promptly condensed, so that the starter was ready for a repetition of the process within a sixtieth of a second.

With an immersion of one millimeter, about 200 amperes was necessary for regular striking of the arc. With less immersion, less current could be used, but with the lesser immersion the mercury would sometimes be thrown mechanically out of contact with the rod and would require several sixtieths of a second to return and make contact again.

## V. THE NEW ARC STARTER

In attempting to develop a starter of the type of the preceding section and also of the type mentioned at the end of 3 in section III, it was discovered that a rod of relatively high resistivity partly immersed in mercury had very extraordinary properties with respect to the initiation of arc cathodes on the mercury surface. The first observations were made on a carborundum crystal. It was found that about ten amperes flowing through the crystal would start an arc cathode, and unlike the tungsten rod of the previous section, this current magnitude for starting the arc cathode varied very little with the degree of immersion of the crystal. The voltage required for starting varied with the length of the crystal above the mercury and was less than 100 volts for moderate lengths.

---

[14] Slepian, TRANS. A.I.E.E., 48, 523, 1929. Dickinson and Baker, TRANS. A.I.E.E., 48, 528, 1929.

The starting of the arc was extremely regular and reliable. Fig. 1 shows an oscillogram of operation of a mercury pool cathode vapor tube with such a starter. The starter electrode was connected to the anode of the tube through an auxiliary external rectifier, and the whole was placed in an alternating current circuit. As will be seen from the oscillogram, in each half cycle of polarity proper for sending current through the external rectifier, an arc was started in the tube.

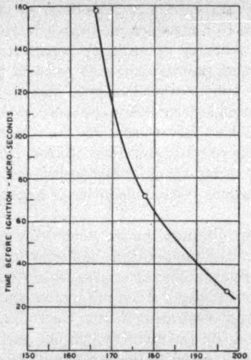

Fig. 2—Curve Showing Variation of Mean Time for Ignition with Voltage

This extraordinary property for starting an arc cathode was found to be generally enjoyed by materials of considerable resistivity. Thus similar results were obtained with starter rods made of lightning arrester resistor material (clay, lampblack mixtures), globar resistors (special carborundum heating elements), galena and ferro-silicon.

No wasting away of the starter rods could be observed even after long periods of operation. Some rods on life test have now been operating sixty times per second, 24 hours per day, for over seven months with no observable deterioration.

The mercury pool was not an essential element in the operation of the starter, as regular operation was obtained with a starter rod partly buried in solidified tin, as well as with a molten tin cathode. Operation was obtained also in air at atmospheric pressure.

The time required for the formation of the arc cathode after the application of the necessary voltage was found to be extremely short. This was investigated with the cathode ray oscillograph by W. E. Berkey. The following results are typical. For a resistor rod of $\frac{1}{8}$ in. diameter in mercury dipping $\frac{1}{4}$ in. below the surface and extending $\frac{1}{2}$ in. above the mercury, the minimum voltage for starting the arc before the rod would heat up appreciably was found to be approximately 130 volts. A sudden application of 250 volts would start the arc within less than five microseconds. As the voltage was reduced, longer time delays between the application of the voltage and striking of the arc were observed. These times varied considerably in test repetitions. Fig. 2 shows the average variation of the mean time with voltage.

## VI. Observations Bearing on the Theory of the New Starter

The insensitivity of the new starter to the degree of its immersion in the mercury indicated that its operation did not depend upon an actual breaking of contact with the mercury. This is confirmed by the operation of the starter buried in solidified tin, and it was also confirmed by operation obtained where permanent electrical contact below the surface of the mercury was insured by means of a tight metal clamp, and also by a copper sprayed portion of the rod below the mercury surface.

When operated just below the voltage required for regular operation, frequent tiny sparks would be observed at the mercury-rod junction. This suggested that the seat of the phenomenon resided at the mercury-rod junction, and also suggested that the operation might take place in roughly two stages, each stage setting different requirements. First would be the starting of a tiny arc cathode, the tiny sparks observed above. This would call for a very high electric gradient, or very large concentrations of energy to effect a thermal explosion at the mercury-rod junction similar to what occurs at the last contact point of separating contacts. Second would be the building up of the small current flowing from this tiny arc cathode to an arc current sufficient to short circuit the rod to the holder or another anode. This would call for the ability of the side of the rod immediately adjacent to the tiny "spark" or arc

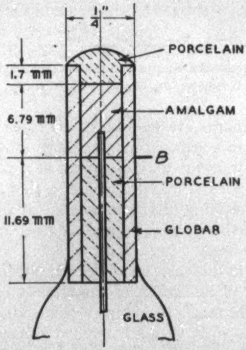

Fig. 3—Diagrammatic Sketch of Apparatus Used to Illustrate the Necessity of a Voltage Gradient for Ignition

cathode to carry considerable current as the anode of an arc.

Both of these requirements seem to call for the existence of an electric gradient down the rod to the mercury-rod junction. The necessity for such a gradient is beautifully illustrated by some experiments of L. Smede.

As illustrated in Fig. 3, a hollow cylindrical starter made of globar was used. Good contact with the internal surface of this cylinder was made up to a level *B* by means of an amalgam. The electrical connection to the amalgam was brought in under the mercury and of course was insulated from the mercury. A barometric connection permitted the mercury level to be raised and lowered. The voltage required by the starter for regular operation was observed for different levels of the mercury. The results are shown in Fig. 4.

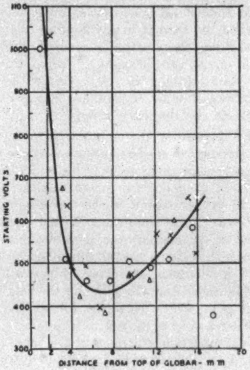

FIG. 4—CURVE SHOWING VARIATION OF IGNITION VOLTAGE WITH LENGTH OF IGNITING ELECTRODE

The impressed potential existed between the internal amalgam and the external mercury. When the mercury level was considerably below *B*, there would be current flow down the cylinder to the mercury from above, and therefore a gradient down the starter to the mercury. As the mercury level approached close to *B*, more of the current would flow across the cylinder wall to the mercury junction, and less down the cylinder wall. Hence for a given voltage, the gradient down the rod would be lessened. Hence if a gradient of a definite magnitude is necessary down the starter at the junction, the voltage required for starting should rise rapidly as the mercury level approaches *B*. This, the curve of Fig. 4 shows to have been actually the case.

## VII. THEORY OF THE NEW STARTER

The observations of the previous section suggest that with respect to voltage and energy concentration, conditions at the starter rod-mercury junction must be similar to those occurring at the last contact point of separating contacts. Electrostatic theory shows that this is the case. Fig. 5 shows the equipotentials and current flow lines for a slab of starter material with parallel plane sides and dipping down a great distance into the mercury. This field distribution is taken from Maxwell "Electricity and Magnetism," 3d edition, Art. 193, p. 297, and assumes that the electrical resistivity of the mercury is negligible compared to that of the starter material. The current and voltage concentration at the mercury junction are quite clear.

From the mathematical formulas of Maxwell in the reference just given, we calculate that the potential gradient along the starter side near the mercury junction is given by

$$\frac{dV}{dx} = \sqrt{\frac{d}{2}}\,\frac{X\infty}{\sqrt{x}} \qquad (1)$$

where $d$ is the thickness of the slab, $X\infty$, the gradient along the slab far from the junction, and $x$, the small distance from the junction at which the gradient $\frac{dV}{dx}$ exists. According to this formula, the gradient, and with it the current density, becomes infinite at the junction where $x = 0$.

Of course, the formula (1) may be considered as applying only so close to the junction as the material may be considered continuous. If we assume that we may consider the material continuous down to atomic distances, that is down to $x = 10^{-8}$ cm, and if we take the slab thickness as 0.5 cm, we have for the gradient at the junction,

$$\frac{dV}{dx} = \sqrt{\frac{0.5}{2}}\,\frac{X\infty}{\sqrt{10^{-8}}} = 0.5 \times 10^{4}\,X\infty \qquad (2)$$

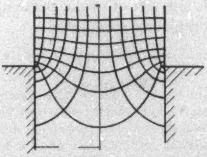

FIG. 5—DIAGRAM OF EQUIPOTENTIAL AND CURRENT FLOW LINES IN A SLAB TYPE IGNITING ELECTRODE

If we adopt as our criterion for the starting of an arc cathode, the appearance of a gradient of $10^6$ volts per cm at the junction, we have for gradient, $\frac{dV}{dx}$ remote from the junction

$$X\infty = 200 \text{ volts per cm} \qquad (3)$$

Actually, less than 100 volts per cm were sufficient for starting an arc cathode with the materials tested. It seems likely that other phenomena peculiar to the carrying of current across contacts appear also at the junction, such as transition films of high resistivity, or the drawing up of small particles forming bridges, as suggested by Holm.[15]

The first requirement for the starting of an arc cathode at the junction then seems to be the impressing of a gradient, $X_\infty$ of the order of 100 volts per cm along the starter rod. This practically sets a lower limit to the resistivity of the rod material, since with ordinary metals and reasonable rod dimensions, the current required to maintain such a gradient would be enormous. We may perhaps set $10^{-2}$ ohms per cm$^3$ as the practical lower limit of resistivity of a starter rod of reasonable dimensions.

The requirements of the second stage of the formation of the arc, however, set an upper limit to the resistivity of the rod. The tiny arc which forms at the junction must grow to a magnitude sufficient to short-circuit the rod. Since the tiny arc first flows to the rod side as anode, the resistivity of the rod must be low enough to permit the flow of sufficient current through the rod side without requiring excessive voltage. Actually, it was found that the voltage required for starting increased with the resistivity of the rod material. We may probably set a few thousand ohms per cm$^3$ as the upper limit for the resistivity of the starter rod.

*Applications of the New Starter.* Applications of the new starter will be obvious to those familiar with grid controlled gas tubes. In such tubes, until now, an arc cathode was permanently maintained by a separately heated thermionic cathode or a keep-alive arc. The starting of an arc to a main anode was then controlled by a grid. Now the permanent arc cathode and control by the grid may be eliminated, and the starting of the arc to the main anode effected and controlled entirely by the new starter. Thus many of the problems associated with the use of grids, particularly for large currents, are completely eliminated.

## Discussion

**H. E. Edgerton:** An arc starter is used at the Massachusetts Institute of Technology for stroboscopic studies of the angular oscillations of synchronous machines, and for taking high speed motion pictures on continuously moving film whereby the starting is accomplished by means of a suddenly-applied high voltage on an external grid or starting band which is located close to the junction of the mercury and the glass. The necessary high voltage is obtained easily and accurately timed by a condenser discharge through a grid-controlled gas-filled tube, such as the thyratron, and a step-up transformer. Further descriptions of the arrangement are contained in an article in the *Review of Scientific Instruments*, October, 1932, p. 535, by K. J. Germeshausen and the writer.

The cathode spot always appears at the junction of the glass and the mercury when an external starter is used. Small spots are seen there even when the anode is disconnected, somewhat as described by the authors. These facts indicate that the starting mechanism may be similar to that described by Slepian and Ludwig, namely, the establishment of a high potential gradient.

The authors have made a valuable contribution to the pool type of mercury-arc tube, and this new starter may aid us in our efforts to get accurately-timed high-speed stroboscopic light.

**W. M. Goodhue:** The physical condition existing in a grid-controlled mercury-arc rectifier or inverter tube has always seemed strained or abnormal for an arc, particularly in an inverter where the anode is positive most of the time *in which the current is not flowing* from anode to cathode. This is an unstable condition and since the cathode is always active, there is always the possibility of the equilibrium being upset by stray ions striking an arc with consequent loss of grid control. The use of the new method described in the paper will tend to remove these strained conditions, since the cathode hot-spot emission has ceased when the current is not flowing. As a consequence stray ions reaching the electrodes are not likely to cause a "misfire," that is, one tube firing at the wrong time and another tube of the circuit failing to fire. Under these conditions, stability exists at the anode, the cathode is acting as a rectifying negative electrode, and the grid is absent.

As stated by the author, the elimination of the grid is an advantage in designing the anode structure. At present, the small glass bulb mercury-arc tubes seem to have lost popularity, due to the necessity of tilting the bulb for starting, and the annoyance of restarting in case of failure of the power supply, unless expensive automatic tilting equipment is used. Also the lack of voltage control of the mercury-arc tube means a disadvantage in comparison with a field-rheostat controlled motor-generator. The successful development of the new device will remove both of these disadvantages and should bring the small mercury-arc tube back into popularity. However, for voltage control, only single-anode tubes can be employed.

An important question concerning the new starter which replaces grids, is the deionization time required for the hot-spot to become inactive. Has the author performed any qualitative or quantitative experiments which would indicate the order of magnitude of this? Another factor which requires consideration is the power that the new starter may require, which may be 1,000 watts or more. This power is much larger than is required by grids except in very large sizes of tube. Is all this power lost as heat in the ignition circuit or is there a possibility that some of this power may be utilized to diminish the cathode drop of the main arc, and therefore cannot all be considered a loss chargeable to ignition? Would it be possible to diminish the ignition power by the use of a starter voltage wave form specially peaked as for example by an auxiliary, saturated transformer so that the starter functions only during the ionization period? After such ignition the arc would maintain itself during the active half cycle.

In addition to describing this particular method of ignition, the paper is very useful to those interested in the subject in that it describes concisely both the physics and application of the several older methods of arc ignition.

**R. E. Hellmund:** In discussing the theory of the new starter, the authors have assumed a smooth surface for the starter and they have shown that with certain resistance values the voltage and current concentration at the starter-rod mercury junction is such as to favor the formation of an arc. In practise, conditions are likely to be even more favorable due to the fact that the starter-rod does not have a smooth surface but a rough contour somewhat as indicated in Fig. 1. The cohesion of the mercury most likely does not permit it to adhere closely to the rod surface in the crevices. This means that there will be point contacts such as at (*a*) and (*b*), a condition which of course brings about much greater voltage and current concentrations than indicated by the formulas in the paper. Instead of having direct contact as in Fig. 1, we may, of course, have contact through small particles as briefly indicated by the authors and somewhat as

---

15. R. Holm, *Wiss. Veröff. d. Siemens-Konzern*, X, 4, 1931.

shown in Fig. 2. Here again the cohesion of the mercury is instrumental in creating point contacts.

A certain similarity in the contact phenomenon just described and the latest hypothesis on contact phenomenon described in a paper by Ludwig and Baker[1] and the discussion which I contributed at the time, is quite obvious.

Figs. 1 and 2 shown here seem to indicate the reason for the absolute reliability of the starter-rods in their functioning. If we assumed, for instance, that the phenomenon first takes place at (*a*) but is not sufficient to create a sufficiently sustained cathode spot, another spot is immediately available at a second point (*b*), etc. Thus proper operation is always assured.

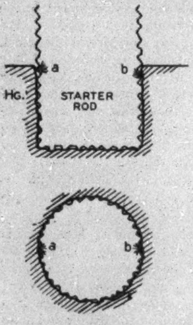

FIG. 1

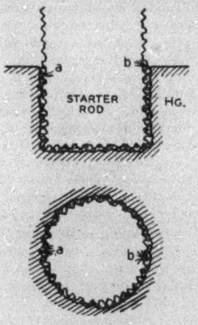

FIG. 2

**D. D. Knowles:** Engineers are familiar with the existing types of grid-controlled gas and vapor filled tubes known under the trade names grid-glow tube, thyratron, trionode, etc. These tubes usually made with hot filament cathodes in an atmosphere of mercury vapor, or one of the noble gases such as neon, argon or helium are splendid devices for the control of relatively small amounts of power and for performing various automatic functions where speed of response, silent operation, extreme sensitivity, or innumerable operations without deterioration are required. They are especially well suited to handle relatively small currents, say up to 100 amperes, at voltages even as high as 20,000 to 30,000 volts.

For power conversion purposes and the control of heavy industrial apparatus, however, they have 3 distinct limitations:

1. The overload capacity consistent with long life is limited. This is due to the fact that the cathode has a definite capacity to emit electrons, this capacity depending upon the type of coating, the operating temperature, and the area. Any current in excess of this limiting value damages the tube to an extent depending upon the overload and the length of time it exists.

2. Considerable energy is required to maintain the cathode at its operating temperature, the actual value, of course, increasing as the size of tube increases.

3. A considerable time is consumed in putting these tubes into service. This is especially true of large tubes and is due to the time required for the filament to reach operating temperature. In some tubes this delay is as much as 30 minutes.

An obvious solution to at least 2 of these limitations would seem to exist in the use of a mercury pool cathode instead of a hot filament. When this is attempted, certain difficulties immediately appear. To begin with, the conventional pool requires a keep-alive arc which means a considerable amount of energy for excitation and complications in the circuit. It also is necessary to provide a means for starting the keep-alive arc. Such means are at the best cumbersome and expensive. What is even more important, the presence of ionization from the keep-alive arc makes it difficult adequately to control the main discharge by means of a grid. These difficulties appear to be eliminated by the igniter electrode described by Messrs. Slepian and Ludwig.

The usual starting mechanism and keep-alive is eliminated because the igniter electrode starts the arc on each positive half cycle.

Whereas the grid in a grid-controlled tube is varied in phase to *allow* the arc to start at a predetermined point in the cycle, the igniter voltage in the new tubes may likewise be varied in phase to determine the point in the cycle at which the arc will be *ignited*. The outward effect—the change in average current output with phase angle, is therefore the same.

There is no delay in starting, such as that required to heat a filament, and the large overload capacity characteristic of mercury pools is, of course, inherent.

It is not surprising, of course, that such a device should have some limitations. In small tubes its utility is somewhat limited at least for the present, by the fact that the maximum current required in the control circuit is of the order of amperes instead of microamperes as in grid controlled tubes.

It is obvious also that a glass tube containing a pool of mercury must be handled with a little more care than is necessary with other types. This objection, however, is not very serious as is proved by the successful use of mercury pool glass rectifiers in this and other countries.

Considering the advantages and disadvantages of this new development, however, it appears beyond any doubt, that a new line of tubes employing this principle will very shortly become one of the most valuable members of the industrial tube family, thus beginning a new era in the conversion and control of power by electronic means.

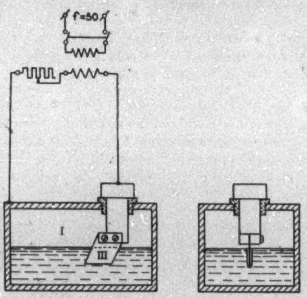

FIG. 3—SINGLE-ANODE MERCURY ARC RECTIFIER WITH IMMERSED ELECTRODE

**Othmar K. Marti:** This investigation of various means for initiating a cathode arc is of great value. In this connection, I would like to call attention to some earlier work along this line.

The initiation of an arc by the use of a high-resistance electrode partly immersed in the mercury cathode was proposed in connection with the early work on the mercury vapor lamp, mention of this being made in British patent No. 13,084, dated June 9, 1904, by Butler-Burke.

In connection with the investigation of cathode phenomena, experiments with a tungsten electrode, partly immersed in mercury and producing a cathode arc, were made in the laboratory of Brown, Boveri and Company, Limited, of Baden, Switzerland, of which an abstract was published in *The Brown Boveri Review* for November, 1929, pp. 303-305, in an article by Mr. A. Gaudenzi. Fig. 3 is a reproduction of Fig. 1 of this article. In it, *III* is the tungsten electrode, 0.3 mm thick, partly immersed into the mercury cathode pool of vessel *I*. When current was passed through the electrode and the mercury, the tungsten electrode became heated, vaporizing the mercury adjacent to it, and producing a layer of mercury vapor between the electrode and the mercury, thus breaking the contact, and producing an arc. The total voltage drop in this arc was approximately 10 volts, which consisted entirely of the cathode drop. It would be interesting to know what voltage drop was observed by Messrs. Slepian and Ludwig when making their investigation.

---

[1] *Influence on Commutation of Brush Contact Drop*, A.I.E.E. TRANS., Dec. 1932, p. 959.

According to an oscillogram in the article by Gaudenzi, the apparatus acted as a rectifier, permitting currents up to 230 amperes to flow in only one direction, during the positive half-cycle, and blocking them during the negative half-cycle. It is conceivable that such a device could be used as a rectifier with a very low arc drop (10 volts). In the experiments it was found, however, that the rectifying action ceased when the inverse voltage during the negative half-cycle exceeded 100 volts, so that the application of this apparatus as a rectifier would be limited to low voltages.

The experiment was made with a 50-cycle supply, and, according to the oscillogram in the article, the current flow started regularly every cycle.

The controlling of the point in the cycle at which the main arc to the anode is started, by timing the ignition of the cathode arc, as suggested by the authors, was proposed by P. H. Thomas as early as 1905, as is disclosed in some of his patents.

We would like to take issue with the statements made in the last paragraph of the paper, which seem to infer that unsolved and difficult problems are associated with the use of grids for controlling the firing of the main anodes, and that the method as proposed by the authors would eliminate such problems. In the first place, in the rectifiers manufactured by the company with which I am associated, no difficulties have been experienced in controlling the firing of the anodes with properly designed grids, and no difficulties were experienced with their design or construction. In the second place, it seems rather premature for the authors to state that no difficulties will be experienced in the commercial application of the method proposed by them for controlling high-current rectifiers. In the third place, it seems to be apparent that their method is applicable only to mono-anodic rectifiers, and could not be applied to poly-anodic rectifiers, where the cathode arc burns continuously. It also is evident that more power will be required for controlling the firing of anodes by the method proposed by the authors than with grid control, for which only a small fraction of an ampere, at 100 volts or less, is required to control the firing. The ratio of the controlled power to the controlling power therefore is greater with grid control than in the method proposed by Messrs. Slepian and Ludwig.

**A. W. Hull:** We have checked some of the values reported in this paper, using thyrite as the semi-conductor. For the sample of thyrite used, an average voltage gradient of 600 volts per cm gave reliable starting. This is consistent with the values given by the authors.

This method of initiating arc cathodes puts at our disposal an additional means of control over vacuum arcs, which is sure to find valuable applications.

**J. Slepian and L. R. Ludwig:** The question of deionization time which Mr. Goodhue raises has a somewhat different significance in the igniter-controlled tube than in the usual grid-controlled tube. In the latter, a certain time is necessary for the ion density in the neighborhood of the grid to fall to so low a value that the grid is able to prevent the re-establishment of the arc to the anode. In the igniter-controlled tube, it is the cathode spot of the arc itself which must disappear during the period of reversed voltage. With a cold cathode, as in the mercury pool arc, this cathode spot disappears extremely quickly. Our own experiments indicate that this disappearance takes place in less than a few microseconds. However, this does not mean that high voltage can be applied to the tube immediately after the disappearance of the cathode spot, since there always is the probability of "backfire" and the establishment of a new cathode spot. The probability of backfire is large while the residual ionization is large, and the probability of backfire decreases to zero as the density of residual ionization decreases to zero. Thus, the question becomes—how long does it take for the ion density to fall to so low a value that the probability of backfire is negligible? This question has not yet been investigated in careful detail, but our first experiments indicate that a few hundred microseconds will be more than enough.

As Mr. Goodhue mentions, the instantaneous power in the igniter is large compared with that required by a grid, but the mean power can be made small by using suitable circuits which will supply this power only at the moment it is needed, and only until the arc is struck, but even with these means, the power required by the igniter probably will be larger than that used by a grid. For small power applications this may be a considerable disadvantage for the igniter, but for large powers we do not believe that it is important. The power consumed by the igniter has no effect upon the arc drop in the vessel. The cathode spot of the arc moves away from the igniter as fast as it is struck and during most of the half cycle may be a centimeter or more distant from it.

The account of the work by Gaudenzi given by Mr. Marti is very interesting, but, of course, is not an example of striking the arc by means of a high resistance igniter electrode. It comes rather under the classification "the light contact arc starter" which is described in section IV of the paper. The voltage drop which is observed when the arc is started by the igniter and flows to the igniter holder is about 10 volts.

Mr. Marti seems to be extremely sensitive to any suggestion that there are any difficulties in connection with rectifiers or the application of grids to rectifiers.

The only place where problems are mentioned in the last paragraph with which Mr. Marti takes issue is in the last sentence "thus, many of the problems associated with the use of grids, particularly for large currents, are completely eliminated." We do not say that these problems are insoluble or even that they are not yet solved, but merely that there are problems. Mr. Marti himself admits that, when he requires that his grids be "properly" designed. Such proper design must certainly be for the purpose of preventing some difficulty which otherwise would ensue. Does Mr. Marti suggest that the heating of grids and the rise in the arc drop which they produce present no problems to the designer?

We do not state, as Mr. Marti says, that no difficulties will be experienced in the commercial application of the new method for controlling high current rectifiers. We simply state that elimination of the grid certainly eliminates many of the problems relating to the grid. Of course, the new igniter introduces problems of its own, but we believe that for high power purposes, these problems can be solved in a better fashion than the problems imposed by the use of the grid. Our further experience with the igniter is confirming this belief.

As mentioned heretofore, the power required for operating the igniter will be much larger than that required by a grid. However, if we charge against the grid, the power lost due to the increase in arc drop which the grid produces, then the situation is reversed. The igniter then dissipates less power than the grid. The question as to how much power is required to control the igniter does not seem to us to be a very important one for large power applications. For example, for a 1,000-kw controlled rectifier, the question as to whether the igniter takes 1 kw or 1 milliwatt, seems to us to be very less important than the degree of reliability and sturdiness of the controlling device.

# Applications of Harmonic Commutation for Thyratron Inverters and Rectifiers

BY C. H. WILLIS*
Member, A.I.E.E.

***Synopsis.**—The problem of commutation in thyratron rectifiers and inverters is discussed and a method of using a harmonic circuit of reduced kva to force commutation is described.*

*By the aid of harmonic commutation, inverters can be operated to supply lagging loads and rectifiers can be phase controlled in the leading quadrant. A rectifier which is phase controlled 90 degrees leading becomes equivalent to a synchronous condenser and may be used for power factor correction.*

*A duplex type of circuit is described which enables a polyphase inverter to produce a sinusoidal voltage and current, and permits a rectifier to draw a sinusoidal current from the a-c system.*

*The inverter is shown to differ from a synchronous converter only in that the sum of the a-c and d-c armature reactions of the inverter must always be zero. By providing two sets of tubes in the inverter, one on the unity power factor axis and the other on the zero power factor axis, a crossed axis inverter is developed which will furnish a sinusoidal current and voltage for all conditions of load.*

* * * * *

## INTRODUCTION

COMMUTATION has not been one of the problems to be solved in the development of the mercury arc rectifier. The unidirectional conductivity of the arc, in combination with the variation of the phase voltages, provides an inherent and entirely satisfactory means of commutation for purposes of simple rectification. This process may be designated by the term *phase commutation.*

When the rectifier is provided with thyratron grids, and operated as an inverter for supplying alternating current, phase commutation as used for rectification, may still be employed, provided the load supplied by the inverter has a leading power factor. Phase commutation in an inverter is, however, not so satisfactory as in the case of a rectifier because it lacks inherent stability, and because commercial loads seldom if ever have a leading power factor.

The problem of commutation as presented by the inverter is quite similar to the familiar problem of commutation in continuous-current motors, because of the fact that the thyratron grids are not able to interrupt the current through the arc, but are only able to maintain an open circuit once the current has been stopped.[1] Early in the history of the d-c motor the commutating pole was developed as an aid to commutation and these have proved indispensible in modern machines.

A method of commutating thyratron equipment has been developed which is closely analogous to interpole commutation in continuous current machines. This method of commutating thyratron apparatus employs a harmonic of the fundamental a-c frequency and has therefore been called "harmonic commutation."

A description of *harmonic commutation* may be found in the December issue of the *General Electric Review.*[2] Since this method of commutating inverters and rectifiers has been described only recently, its general features will be briefly summarized before giving certain applications of this type of commutation to inverters and rectifiers.

## HARMONIC COMMUTATION

One method of applying harmonic commutation is illustrated in Fig. 1, which represents the positive commutating transformer $T$ of a six-phase inverter with the thyratron tubes $A$ to $F$ inclusive. At some instant the continuous current is entering through tube $A$ and the commutating voltage may be assumed as shown by the arrow $e_c$. If now thyratron $B$ is fired, the voltage $e_c$ will transfer the continuous current from tube $A$ to tube $B$. After tube $B$ has been conducting for 60 electrical degrees the commutating voltage $e_c$ will have reversed because it has triple frequency, and $e_c$ will then serve to commutate the current from tube $B$ to tube $C$. Thus the harmonic voltage of the commutating transformer may be used to commutate each tube in succession.

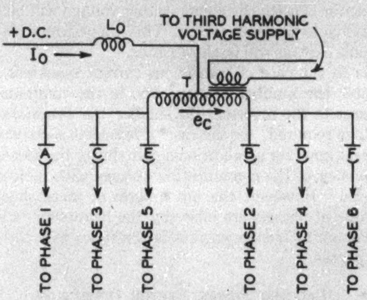

FIG. 1—ELEMENTARY CIRCUIT FOR HARMONIC COMMUTATION

The only condition necessary for satisfactory commutation is that the commutating voltage $e_c$ shall exceed any difference in phase voltage between the tubes under commutation for an interval sufficient to permit the current to transfer and the tubes to deionize.

*Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 23-27, 1933.*

An excessive commutating voltage causes no serious trouble as in the case of commutating poles, because the unidirectional conductivity of the tubes prevents a reverse current, or over commutation.

Any convenient source of voltage may be used to produce the harmonic commutating voltage. A simple and economical method is secured by connecting a static capacitor across the commutating transformer. A portion of the direct current must then flow through the capacitor, and this builds up a voltage opposing the current flow, and therefore in the proper direction for commutation. Since the direct current flows alternately from opposite ends of the commutating transformer, a capacitor across the commutating transformer provides a voltage of triangular shape as shown in Fig. 2. The maximum voltage $E_c$ coincides with the instant of commutation, and the interval $2\alpha$, as shown in the figure represents the conducting period of one tube. When a capacitor is used, the commutating voltage will be proportional to the load current. This is a desirable feature in some cases as will be shown later.

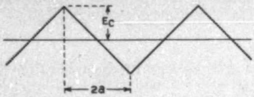

FIG. 2—WAVE SHAPE OF COMMUTATING VOLTAGE PRODUCED BY A STATIC CAPACITOR

As in the case of continuous-current machines, the greater the number of segments, in the commutator, (phases in the inverter) the smaller the commutating voltage required. In the case of *harmonic commutation* there is however an additional gain due to the increased frequency of the commutating voltage with increasing phases. However, the advantages of increasing the number of phases, are offset by the increasing ratio of maximum to average current in the tubes with increasing phases.

### LAGGING POWER FACTOR OPERATION

In discussing the performance of an inverter when supplying a lagging load the operation becomes rather involved. Phase commutation is definitely eliminated as a method of commutation, because this will operate only in the leading quadrant for an inverter. When harmonic commutation is employed, we must provide a commutating voltage $e_c$ which exceeds the difference in phase voltages $e_p$ for an interval sufficient to permit commutation. However the problem of supplying a lagging load from an inverter is more involved than the simple matter of commutation. It is convenient to resolve the problem of lagging loads into two cases:

1. Where the inverter is feeding a system whose voltage wave shape is fixed and practically independent of the current wave as in the case of rotating machinery.
2. Where the voltage wave of the system is a function of the current wave and therefore may become distorted by the current.

### LAGGING POWER FACTOR OPERATION IN PARALLEL WITH SYNCHRONOUS ROTATING MACHINERY

The simpler case where the voltage wave form is definite, corresponds to an inverter operating in parallel with synchronous machines. In considering this case we must bear in mind the fundamental transformer relation that the sum of the primary and secondary load currents in any transformer must be zero at all instants. (Neglecting the exciting current.) When applied to the polyphase inverter network shown in Fig. 3, this principle of transformer operation requires that the output current of the inverter shall be symmetrical about the axis of conduction of the tubes. This idea is quite important for an understanding of the behavior of an inverter when supplying lagging loads. Stating this fact differently, we see that since the load currents are drawn from the d-c circuit, the output a-c currents must at any instant be symmetrical about the axis on which the continuous current is supplied. If we compare the inverter to a synchronous converter we find that the condition just stated is equivalent to stating that the sum of the a-c and d-c armature reactions in the inverter must at all instants be zero.

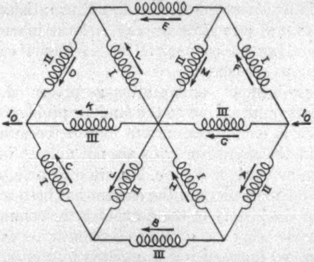

FIG. 3—RIGID 6-PHASE INVERTER NETWORK

This may be illustrated for a six-phase network composed of three separate transformers by referring to Fig. 3. If we represent the currents by the letters as shown, it is easy to prove that

$$A + M + J + D = F + L + H + C \qquad (1)$$

Therefore the load current of transformer (I) must equal the load current of transformer (II) during the entire interval that the continuous current is entering as shown. However transformer (I) has just been commutated while transformer (II) is next to be commutated. If the d-c supply current be constant, the current wave shown in Fig. 4 is the only current wave form possible per transformer secondary. In any case with a balanced load the current during the interval $t_3$

to $t_4$ must be a repetition of the current during the interval $t_1$ to $t_2$.

If now the axis of conduction of the tubes be shifted with respect to the voltage by changing the phase of the grid supply, the current output of the inverter may be given any phase relation desired as shown in Fig. 4. Here the inverter is shown supplying a current lagging the voltage by an angle $\beta$. An inverter may thus be made to supply load at any desired power factor by merely adjusting the phase of the axis of conduction with respect to the a-c voltage wave. However, once the phase of the axis of conduction has been set, the inverter must supply its current at this power factor and no other.

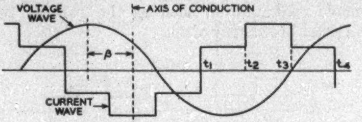

Fig. 4—Current Wave Shape in Secondary of a Network Transformer of a 6-Phase Inverter

When an inverter is operated in this manner it becomes equivalent to a synchronous converter, excited for normal a-c line voltage, with the brush position variable at will. The power factor of the alternating current depends on the brush position, and also the ratio of the a-c to the d-c voltage depends on the brush position, and therefore on the power factor. By the aid of harmonic commutation a tube converter can be commutated through the entire circle of 360 degrees as shown in Fig. 5. We may operate through 180 degrees as a rectifier, using phase control of the d-c voltage in either the leading or lagging quadrants, and we may operate through the entire inverter semi-circle supplying loads at any power factor desired from zero leading to zero lagging. The tube converter differs from the synchronous converter only in regard to armature reaction. In the tube converter the sum of the a-c and d-c armature reactions must at all instants be zero as a consequence of relation 1.

When operating as a rectifier in the leading quadrant the d-c voltage decreases as the power factor decreases. With the voltage approximately zero we may short circuit the d-c output and the rectifier then becomes the equivalent of a synchronous condenser in that it draws a leading current from the a-c system. The commutating kva required here will be a maximum because the difference in phase voltage *ep*, is a maximum at the instant of commutation and opposes commutation. The amount of load is determined by the phase of the grids. If the firing of the grids is delayed slightly the equivalent rectified direct current is increased and therefore the circulating current and kva drawn from the a-c system increases.

## Lagging Power Factor Operation Without Parallel Synchronous Rotating Machinery

The case where the inverter is supplying a load whose voltage wave form is a function of the current wave is further complicated by the fact that the inverter so far described can supply only the current wave form shown in Fig. 4. If now we load this inverter with a load composed of a resistance and inductance in parallel, the voltage wave will be distorted as shown in Fig. 6. The effect of this distortion is to increase the effective value of the voltage and also to make commutation more difficult. With a small amount of lagging load this effect is not serious, but it presents a problem which may be serious in a number of applications.

To illustrate this, we will assume a six-phase inverter whose voltage wave form for phase 1 is shown in Fig. 7A. We will now assume a load which consists of resistance and inductance in parallel. The resistance component of the current is shown in Fig. 7B. The inductive current is shown in Fig. 7C and the total current for some ratio of resistance and inductance is shown in Fig. 7D. The instantaneous power of phase 1 under the conditions of load assumed, is shown in Fig. 7E. With a balanced load the total power must be as shown in Fig. 7F.

The direct current must be supplied at a constant voltage to give the phase voltage wave form shown in Fig. 7A; therefore when the load is partly inductive the continuous current supply, which is proportional to the total power, must be pulsating as shown in Fig. 7F. With loads which are largely inductive the supply current would become actually alternating.

Fig. 5—Power Factor Circle for Inverter and Rectifier Operation

Of course this ripple in the supply current can be smoothed out with a filter. However this complication of a pulsating power is not inherent in the inductive load but is introduced by the fact that the voltage wave was a stepped wave. A sinusoidal wave of voltage would eliminate the necessity for a pulsating power supply, and be much more satisfactory in many other respects. It therefore appears that the output voltage wave of an inverter must be a close approximation of a sine wave for satisfactory operation under all conditions of load.

## SINE WAVE INVERTER

The cause of the poor voltage and current wave forms is inherent in the fact that the point at which the direct current enters the network advances by discrete jumps rather than by a uniform motion. In order to have uniform motion of the point of entry and yet have a finite number of points of contact (and therefore tubes) it is necessary to have two tubes which are connected to the network on different axes, conduct simultaneously. By varying the proportion of the current carried by a tube we can cause the equivalent point of current entrance to move uniformly from one tube to the next.

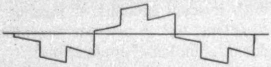

FIG. 6—VOLTAGE WAVE DISTORTION DUE TO AN INDUCTIVE LOAD

One of the circuits which may be employed to accomplish this uniform commutation of the continuous current is shown in Fig. 8. Since the tubes here have been divided into two groups, each group of which will operate as a six-phase inverter, this particular circuit has been called the twin-six.

When tube $A^+$, Fig. 8, is in the middle of its conducting period, the total continuous current is entering through it. The voltage across $C_1$ is then zero and the voltage across $C_2$ is a maximum which we have called $E_c$. If now tube $B^+$ is fired there will be a voltage $E_i$ which will tend to transfer current from tube $A^+$ through the inductance $L$ to tube $B^+$.

$$E_i = \frac{1}{2} e_c - e_p' \tag{2}$$

As condenser $C_2$ discharges and its voltage is consequently reduced, condenser $C_1$ is charged in the reverse direction and therefore the voltage available for transferring current from tube $A^+$ to tube $B^+$ remains approximately constant during the interval in which current is transferring in a given direction. Further, this voltage, $E_i$, increases with $e_c$ which is proportional to the load. Therefore the voltage available for transferring current increases with the current to be transferred and we have approximately the same wave form at all loads. If we make $E_i$ proportional to $I_o$ the wave form will be the same for all loads. The oscillograms shown in Fig. 9 were taken on a twin-six inverter supplying a resistance load. Table I gives the harmonic analysis of the voltage wave of this inverter. The measured value of the current *TIF* was 94, which is not so far from a poor rotating machine.

TABLE I

| | |
|---|---|
| Fundamental | 99.95% |
| 3rd harmonic | 0.9% |
| 5th harmonic | 0.8% |
| 7th harmonic | 0.4% |
| 9th harmonic | 0.9% |
| 11th harmonic | 2.1% |
| 13th harmonic | 1.0% |
| 15th harmonic | 0.8% |
| 17th harmonic | 0.5% |
| Form factor | 1.11 |
| Deviation factor | 7.9% |

Harmonics not given were less than 0.2%

There are several features of the duplex circuit using harmonic commutation such as the twin-six shown above which are worthy of note.

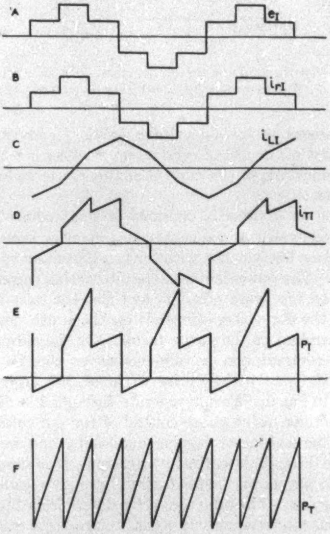

FIG. 7

*A*—Voltage wave shape
*B*—Current wave shape in resistance load
*C*—Current wave shape in an inductive load
*D*—Total current wave for a resistance and inductance in parallel
*E*—Instantaneous power per phase
*F*—Total instantaneous power for 3-phase load or d-c supply current

First, the slow commutation between the two sets of tubes is reinforced by a fast commutation between tubes of one set. Thus we have the normal commutation process reinforced by a reserve process of commutation. In fact one tube may be completely removed from the circuit during operation without a failure of operation. It is hoped that this reserve commutation will make operation more reliable.

Second, anode bombardment should be reduced in this circuit since the current through a tube is gradually reduced to a low value before the inverse voltage is applied, and therefore we should have much less ionization present in the tube at the time of deionization.

Third, the transient voltages incident to rapid commutation are not present in this circuit. For this reason this circuit should be much easier on tubes and transformers than any circuit in which the rate of change of current is very large at times.

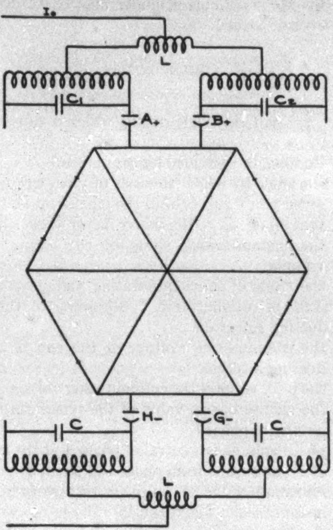

FIG. 8—ELEMENTARY CIRCUIT FOR TWIN-SIX SINE WAVE INVERTER OR RECTIFIER

The commutating voltage required for satisfactory operation of a six-phase full-wave inverter using a static capacitor to produce the commutating harmonic is,

$$E_c = 2\,E_o \sin(\beta + \alpha) \qquad (3)$$

where $E_c$ is the maximum value of the commutating voltage. In the twin-six circuit using static capacitors to supply the commutating harmonic,

$$E_c = \frac{I_o}{4\,f_1 C P} \times 10^6 \qquad (4)$$

where $I_o$ is the continuous current, $f_1$ is the fundamental frequency, $P$ is the total phases, and $C$ is the commutating capacitor on each commutating transformer in $\mu$f.

When the twin-six inverter is supplying a system whose wave form is sinusoidal the best value of the inter-phase reactor depends on the power factor at which the inverter is to supply its load. An exact solution for the best value of $L$ is rather involved. However an approximate value is given by the expression,

$$L = \frac{10^6}{8\,C f_1^2 P^2} - \frac{E_o\,\alpha \sin\beta}{I_o f_1 P} \qquad (5)$$

If we assume unity power factor operation for a 60-cycle twin-six circuit equation (16) becomes,

$$L = \frac{1}{4.15\;C} \qquad (6)$$

where $L$ is in henrys and $C$ is in $\mu$f. A more exact solution than that given in equation (5) may be derived from the circuit relations shown in Fig. 8, but the general solution does not lend itself to a simple numerical calculation of $L$.

The General Electric Company has now ready for test, a 500-kva rectifier using the F.G.41 thyratron tubes and employing harmonic commutation and the twin-six rigid transformer network shown in Fig. 8, to give a sinusoidal alternating current. This rectifier is designed to be supplied from a 4,000-volt, three-phase, 60-cycle circuit and to operate at zero leading power factor as described above.

This apparatus will function as a synchronous condenser and may be given the same load characteristics as a rotary synchronous condenser, but without many of the complications and disadvantages of rotating machines. The rectifier operating as a condenser will lack the ability to hunt and cannot drop out of synchronism. The losses will be lower than those of a rotating synchronous condenser of equal rating.

FIG. 9—OSCILLOGRAM OF TWIN-SIX SINE WAVE IN OPERATION

## VARIABLE POWER FACTOR LAGGING LOADS WITH A SINE WAVE INVERTER

We will now consider the problem of supplying a variable power factor load such as an induction motor from an inverter. We may now employ a duplex type of circuit such as the twin-six circuit described above to eliminate the necessity for a pulsating supply current. However there still remains the difficulty that the alternating currents must at every instant be symmetrical about the equivalent point of continuous current entrance. An inverter supplying a variable power factor load is closely analogous to a synchronous converter operating under similar conditions but with the restriction, noted before, that the inverter is equivalent to a synchronous converter in which the a-c and d-c armature reactions must always exactly cancel. The inverter has no separate field excitation to cancel any difference between the a-c and d-c armature reactions.

With this restriction a rotary converter to supply a variable power factor a-c load would require two sets of brushes operating on different axes. Then as the power factor of the load varied the proportion of the current supplied through a set of brushes would vary correspondingly. Thus if we have brushes on two axes the resulting axis of current supply may be at any point between the axes of the two sets of brushes. For the widest range of power factor variation one set of brushes should be on the axis of maximum voltage and the other set of brushes on the axis of zero voltage.

Returning now to an inverter; if we have one set of tubes operating on the axis of unity power factor load and another set of tubes operating on the axis of zero power factor load, or operating as a synchronous condenser the inverter may supply any load from zero lagging to unity power factor.

In the inverter, as the load becomes more lagging, there will be a tendency for the voltage across arc *VN* Fig. 5, to increase, while the voltage across arc *NU* will decrease. This will result in a circulation of current along the axis *NS* through the tubes which are operating as a condenser. Thus the current in the inverter is automatically divided into two parts and the tubes operating on axis *UV* supply the power component of the current from the d-c system while the tubes operating on axis *NS* short-circuit the wattless component of the current. An inverter as just described, having two sets of tubes on different axes may be referred to as a crossed or quadrature axis inverter.

The chief difficulty encountered in operating a quadrature axis inverter lies in the fact that the commutating voltage of the tubes operating on the zero power factor axis must have a value sufficient to maintain commutation at light loads. For the same a-c wave shape for all loads the commutating voltage of the tubes operating on the unity power factor axis should vary according to the relation

$$E_c' = bI_o' \qquad (7)$$

where $b$ is a constant determined by the condition of satisfactory commutation and $I_o'$ is d-c current necessary to supply the power. The tubes operating on the zero power factor axis should have a commutating voltage which varies according to the relation

$$E_c'' = E_p + bI_o'' \qquad (8)$$

$I_o''$ is the d-c equivalent of the reactive power which must be short-circuited.

With these conditions fulfilled the twin-six crossed-axis inverter will supply lagging loads of any amount and power factor without voltage wave distortion.

The work described above was done in the Research Laboratory of the General Electric Co. The author wishes to express his appreciation of the great assistance given by Messrs. Louis Klauder and G. C. Nonken, in the work described.

### NOMENCLATURE

$\alpha = \dfrac{\pi}{P}$ half the angle during which a tube is conducting, or $\pi$ divided by the phases.
$\beta$ = the angle by which the axis of conduction for a given phase lags behind the maximum voltage in that phase. (*i. e.*, the power factor angle.)
$e_c$ = the instantaneous value of the commutating voltage.
$e_o'$ = the value of the commutating voltage at the instant of commutation. (Beginning of the conducting interval.)
$e_c''$ = the commutating voltage at the end of a conducting interval.
$Ec$ = the peak value of the commutating voltage.
$e_1$ = the instantaneous value of the phase voltage to neutral of phase 1.
$e_1'$ = phase voltage to neutral of phase 1 at the instant of commutation from phase 1 to phase 2.
$E_m$ = maximum value of the phase voltage to neutral.
$e_p$ = instantaneous difference in voltage of two consecutive phases.
$e_p'$ = difference in voltage of two consecutive phases at the instant of commutation.
$E_p$ = the maximum difference in voltage of two consecutive phases.
$E_i$ = voltage available to transfer current from a tube in one set of a twin six inverter to a tube in the other set.
$E_o$ = maximum possible average value of the d-c voltage.
$E_{dc}$ = average value of the d-c voltage. (Phase controlled.)
$E_t$ = maximum voltage across a tube.
$f_1$ = the fundamental frequency of the alternating current.
$f_c$ = the frequency of the commutating voltage.
$I_o$ = the d-c line current.
$I_a$ = the average current through a tube.
$P$ = the number of phases in the inverter or rectifier.
$T_c$ = the time available for commutation.
$T_d$ = the deionization time of a tube.
$T_t$ = the time required to transfer current from one tube to the next.
$\omega$ = the electrical velocity in radians or $2\pi f_1$.

## Discussion

**P. M. Currier:** This paper should be of particular interest to those who have studied and worked with inverter circuits. As Doctor Willis intimates, circuits using phase commutation are at a disadvantage when one attempts to apply them to loads of commercial power factors. He has shown how by the use of harmonic commutation static equipment can be built that practically duplicates the characteristics of direct or inverted rotary converters, and synchronous condensers.

The sine wave inverter described has particular merit in that the a-c vectors have a continuous, almost uniform, motion instead of progressing by jumps as in some other circuits. The transformer windings appreciate this and do not give the transient voltages which are incident to a jumping vector.

It is of particular importance to note that commutation is given two chances to take place. If the first slow commutation should not function properly for any reason, it is reinforced by a fast commutation at the time the next commutating step occurs.

**W. M. Goodhue:** In discussing the inherent stability of inverters, it should be noted that much depends on the type of high-voltage d-c transmission system used. For example, in a constant-current system, the failure of one tube to operate at the proper instant (misfire) is not likely to cause a heavy short-circuit of the d-c system through the low resistance d-c path of tubes (now firing) and the transformers. Also the employment of a synchronous condenser (with low leakage-reactance and with damper windings), in place of static condensers or harmonic commutation, gives a reserve transient source of almost constant potential due to the inability of the cross-gap flux, which links the damper windings, to change suddenly except by becoming peripheral leakage flux, etc., with very heavy currents. If the grid excitation is fed from this same synchronous condenser, there is no hunting between inverter and condenser.

Two questions are asked in the following:

(1) Will a large load on one phase of an inverter employing harmonic commutation cause interruption of service? (2) Does this circuit require a special grid circuit wave form to prevent uncontrolled rectification and consequent d-c short-circuit when carrying lagging loads?

So far as the d-c or average values of current and voltage are concerned, the tubes of different phases operate in parallel (Figs. 1 and 8), with the result that the d-c voltage of the inverter set is definitely limited to less than the rated peak stresses of the tube (15,000 volts maximum for FG 41, according to *G. E. Review*, Dec. 1932, p. 626, Fig. 8). Therefore, in the opinion of the author, what method should be used to meet commercially the demands of high voltage d-c transmission without employing too many tubes?

The sine-wave inverter of Fig. 8, that is, the twin-six circuit, may be regarded as having twelve phases, since each group of six of the twin sixes are out of phase with each other by 30 deg; also the circuit employs inductance lag for dragging out the commutation period. Could not a simple twelve-phase inverter, employing phase commutation, *with transformer leakage flux between anode coils* to drag out the commutation also produce a passable sine wave of current within its operating range, of leading load, obtained by a synchronous condenser? (Note: with a constant-current d-c system, the alternating current and alternating current voltage may both be constant in magnitude, the phase angle varying with load.)

A constant-current high-voltage d-c system has many advantages in addition to those named above: (1) the prime electrical source consists of alternators; (2) because of the large armature reaction usual with modern alternators, they may easily be inherently constant-current machines rather than constant-potential machines, so that automatic regulators for them should be easier to design than for constant-potential machines as is customary at present and (3) the current need never be suddenly interrupted but by-passed instead, so that the use of circuit breakers is possible with constant current, while with constant-potential direct current a short circuit *on a branch line* will shut down the entire system, since circuit breakers on constant-potential direct current can operate successfully only at zero current.

**A. W. Hull:** The possibility of a gradual, instead of abrupt, transfer of current from one tube to the next, which Doctor Willis has accomplished by his duplex circuit, solves the most serious life problem of sealed-off thyratron tubes, *viz.*, that of the damage done by the ions which are left in the space when the anode voltage reverses. It is well known that these ions delay the regaining of grid control, the so-called deionization time, and that their impact on the anode may initiate reverse current or arc-back; but it is not generally realized that they may be numerous enough to cause severe sputtering of the anode, sufficient to coat over insulating surfaces, impair vacuum, and contaminate the cathode surface.

The following example will show the order of magnitude of this disintegration:

A pair of small phanotron tubes with graphite anodes 2 cm in diameter were operated in a single-phase rectifier at 2,000 cycles, 2,700 volts rms, supplying ¼ amp to a resistance load. At the end of 135 hours they failed from loss of emission, and examination showed that the anodes had been eroded to a depth of 1 mm over their whole surface. This effect is exaggerated at high frequencies, because the anode voltage attains high negative values before the ions have disappeared; but it is important even at 60 cycles. Doctor Willis has shown us how to avoid it by transferring the current so gradually that there are practically no ions present when the anode voltage reverses.

The high ratio of peak current to average current, which Doctor Willis has referred to as partially offsetting the economies of a large number of phases, need not be looked upon as objectionable, nor appreciably more expensive, if the tubes are designed with this in view. It appears that a number of the most useful circuits require a ratio of 12 to 1, and it is probable that future tubes will be designed for this ratio.

**C. W. Lampson:** The General Electric Company at Pittsfield has built a thyratron converter utilizing the twin-six principle and operating at zero power factor. This converter has now been under test for a period slightly over six months. During this time we have had an opportunity to verify the essential correctness of principle of harmonic commutation as applied to a polyphase inverter or rectifier.

One incident in the early stages of the test admirably illustrates the third point which Doctor Willis has made concerning the reduction in transient voltages afforded by the gradual shift of current from one tube to another. The current shifting circuit was so adjusted that the rate of shift was reduced leaving a tube conducting a considerable amount of current at the instant of commutation. Very high transient voltages were immediately in evidence on the tube panels, being sufficient to spark over a two-inch gap between the tube and ground. The restoration of the rate of current shift to normal immediately reduced these voltages to a low value.

Oscillograms taken of the current drawn by this rectifier from the line indicate that it is substantially a sine wave at full load. At lower loads the wave shape is distorted to some extent but means can be provided to maintain this wave shape constant at all loads. Measurements of the loss of the rectifier operating at approximately zero power factor indicate that efficiencies of 97 to 97.5 per cent can be obtained corresponding to a loss angle of

14 to 18 degrees. This efficiency could undoubtedly be bettered in a larger model.

It is particularly interesting to note that the zero power factor rectifier imposes the hardest duty on the tubes that will be obtained in any power device. In an inverter, ability to hold off forward voltage is important. In the rectifier, ability to withstand inverse voltage is important, but in this device both forward and inverse voltages of considerable magnitude must be withstood. The ability of the tubes to operate satisfactorily in this application certainly indicates that successful converters of other types can be built.

The rectifier being continuously variable in amount of leading kilovoltampere drawn and having no moving parts is particularly amenable to automatic control.

**R. G. McCurdy:** The use of vapor discharge devices for rectifiers and inverters creates some very interesting problems for the engineer concerned with the inductive coordination of power and telephone systems.

Two distinct problems are introduced, one concerned with the a-c components in the voltages and currents of the d-c systems, and the other concerned with the departure from sinusoidal wave shape of the voltages and currents on the a-c side. For the d-c side, experience with the mercury arc rectifier has shown that the solution is not difficult. With 6- or 12-phase operation and with filters of practicable cost the a-c components in the d-c system can be reduced to magnitudes which permit satisfactory coordination with telephone systems.

On the a-c side, the problem appears more difficult. In cases where a rectifier forms an important part of the load on a power system or where it is supplied over a circuit of comparatively high impedance at the harmonic frequencies, distortion of the voltage wave shape may be considerable, and noise in exposed telephone circuits may result.

This aspect of the rectifier problem is being actively studied at present by the Joint Subcommittee on Development and Research of the N.E.L.A. and Bell System.

The difficulties with the a-c side of rectifiers have naturally created some concern regarding the possible effects of inverters, looking forward to some of the proposals which have been made for d-c transmission accompanied by inversion and distribution at a-c frequencies at various load centers. It is encouraging to note from the paper that there is a considerable advantage from the standpoint of satisfactory commutation in the inverter when the output current has a reasonable approach to a sine wave shape. Judging from the analysis given in Table I of the paper and the measured value of current *TIF* quoted, some advance has been achieved in this respect over the waves encountered with many mercury arc rectifiers in commercial operation. It seems highly desirable to recognize the inductive coordination aspects of this development in its early stages and well in advance of the commercial application to operating systems.

**H. C. A. Sabbah:** Harmonic commutation has also been applied by the writer.[1] In fact, the criterion given on pages 294 *et seq.*, of the above references shows that all series type circuits can be used to supply variable lagging power factor loads. All polyphase circuits which use interphase transformers come in this class also, if the interphase transformer is shunted by condensers or by a stiff harmonic supply voltage.

The inverter circuit given in Fig. 1 is one which has been worked out by the writer for supplying a load of any power factor. In this circuit the harmonic commutating voltage is supplied to the interphase transformers by the capacitors $C_1$, $C_2$, and $C_3$. Here the capacitors mentioned operate on the 2nd harmonic of the fundamental frequency. It is also interesting to note that these commutating capacitors only have to carry at most ½ of the load current and their size is accordingly reduced. This is due to the fact that they have to carry only the a-c component of the rectified load current per phase. The d-c current is carried by the interphase coils. The fluxes resulting from the d-c currents neutralize in the three phase core of the interphase transformer, which greatly reduces the size and cost of this structure.

Neglecting for the moment the effect on output wave shape, it is only necessary for the purpose of accomplishing practical commutation that the commutating capacitors $C_1$, $C_2$, $C_3$ carry a current of the order of magnitude of the exciting current of the interphase transformer at the 2nd harmonic frequency. This would be sufficient to stiffen the interphase voltage during a period larger than the deionization time of the tubes. From a practical point of view it is desirable to have a good wave shape on an inverter and the writer has found that one of the most economical ways of accomplishing this desirable feature is to connect three capacitors, $C_1'$, $C_2'$, $C_3'$, across the output of the inverter as shown in Fig. 1. The function of these capacitors is to remove harmonics which are causing the wave deformation. To accomplish this purpose they should offer a low impedance to the 5th and higher harmonic currents around the load. The effective value of the sum total of these harmonics is of the order of ⅓ of the load current.

In this circuit current commutation can be made very gradual since the commutating current is only ⅓ of the direct current and the time allowed for commutation may be as much as 60 degrees with a theoretical limit of 240 degrees. With the arrangement as shown, which employs three commutating capacitors, more than one tube can be in a conducting state at one time. This permits us to allow each tube to conduct for a period as much as 240 degrees (see previous reference, page 739). This gives us a good utility factor on the conducting time of the tube and permits them to carry higher momentary loads.

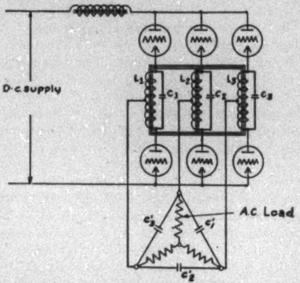

Fig. 1—A Full Wave Three-Phase Inverter Using Second Harmonic Commutation

**C. H. Willis:** The specific questions of Mr. Goodhue may briefly be answered as follows.

1. Any polyphase inverter will operate with a considerable load unbalance. However, when there is no parallel rotating machinery the current unbalance causes a compensating voltage unbalance because there is no energy storage in the inverter. The d-c energy is supplied in a steady stream and therefore the sum of the polyphase circuits must absorb energy at a constant rate.

2. The grid voltage of any inverter must be negative during the entire non-conducting interval of the tubes. Harmonic commutation offers no advantages in this respect.

3. The problem of high-voltage inverter operation may be solved either through the use of higher voltage tubes or by employing series inverter units. This problem is rather in advance of the present stage of development.

4. Any improvement of the wave shape by the use of leakage reactance involves a corresponding reduction of the power factor of the load. This reduction is of serious magnitude where phase commutation is used. It has the further disadvantage that the wave shape varies greatly with the load. The twin-six circuit has the advantage of giving practically the same wave shape for all loads.

---

# PREFACE

This final number of Volume 52 of the QUARTERLY TRANSACTIONS of the American Institute of Electrical Engineers is of unusual importance for several reasons:

1. It completes the Institute's published records of technical papers and related discussion for the year 1933.

2. It embraces in a single bound volume the same scope of material that customarily has been included in separate quarterlies, one dated September and the other dated December.

3. It closes the six-year era of QUARTERLY TRANSACTIONS.

4. It contains a comprehensive and generously cross referenced subject index and author index covering all quarterly issues of the TRANSACTIONS for 1933; also includes reports of the Board of Directors for 1932 and for 1933.

In effect, there are in this single bound volume two quarterly numbers of the TRANSACTIONS, embracing material as follows:

1. In the September section (pp. 711 to 944)

   All technical papers and related discussions presented at the Institute's North Eastern District (No. 1) meeting held at Schenectady, N. Y., May 10-12, 1933;

   Part of the papers together with their associated discussion, presented at the Institute's 49th annual summer convention held at Chicago, Ill., June 26-30, 1933.

2. In the December section (pp. 945 to 1153)

   The remainder of the technical papers and associated discussion presented at the 1933 summer convention; 1933 technical committee reports and reports of the Board of Directors for 1932 and for 1933; composite reference index for 1933.

By combining these two quarterly numbers of TRANSACTIONS into this single bound volume, it has been possible to effect some necessary savings in costs without diminishing the material included in the TRANSACTIONS; also to obviate certain delays otherwise beyond control, thus making possible the distribution of the December contents much earlier than has been possible in the past.

As discussed extensively in several articles appearing in ELECTRICAL ENGINEERING during the latter half of 1933, and as contained in notices to all TRANSACTIONS subscribers, the 1934 A.I.E.E. TRANSACTIONS will be issued in December 1934 as a single bound volume embracing the contents of the 12 monthly issues of ELECTRICAL ENGINEERING for that year. By thus obviating the discrepancy that has prevailed between the total contents of ELECTRICAL ENGINEERING for a given year and the contents of the bound volumes of TRANSACTIONS, the annual volume of TRANSACTIONS will become a complete reference record of all technical and related material published by the Institute for the current year.

# The Electrical Characteristics of Impregnated Cable Papers

BY C. L. DAWES*
Member, A.I.E.E.

and

P. H. HUMPHRIES†
Associate, A.I.E.E.

IN CONNECTION with the investigation of ionization in impregnated-paper insulated cables conducted at The Harvard Engineering School under auspices of the impregnated-paper cable research committee of the National Electric Light Association, it was found necessary to determine over a considerable range of voltage gradient, temperature, and frequency, the electrical characteristics of cable papers impregnated with different cable oils and compounds. The impregnation was conducted under almost ideal laboratory conditions so that little if any gas was occluded. When the results of the measurements were rationalized and analyzed, it was found that to a remarkable degree they all conformed to the same general laws. These laws and the analyses of the electrical characteristics into components may appear to be only empirical. However, they are results of some fundamental causes, involving probably molecular and intramolecular reactions. Therefore, aside from any value which the results presented may have as engineering data, they may at some time be of value in confirming or in disproving some more fundamental theories of dielectrics. Moreover, it is found that actual cables when impregnated so thoroughly that they manifest no appreciable ionization, have electrical characteristics comparable to those obtained with these samples impregnated under almost ideal conditions. Hence the characteristics of impregnated cable paper given here are available as standards with which cables may be compared.

## APPARATUS

Each sample consisted of twelve flat circular sheets of wood-pulp paper, each sheet being approximately 6.5 to 6.7 mils (0.165 to 0.170 mm) thick and having a diameter of 15 in. (38.1 cm). Details of the apparatus and method of impregnation are given in bibliography reference No. 2, although minor improvements have since been made. Briefly, both the cable paper and the compound were subjected to a drying process for approximately 9 hr at 105 deg C and at a vacuum better than 2 mm of mercury. For approximately 21 hr longer, during impregnation and after the complete impregnation of the sample, the temperature and the vacuum were maintained at the values stated. Hence, the completed samples should contain, either in absorption or as voids, only the slightest traces of gas.

In these particular tests, three cable oils, widely divergent in their physical characteristics, were used. Compound (or oil) *A* is a light clear oil of low viscosity and is described as follows: "a light oil especially prepared so that amorphous constituents are removed." Its Saybolt viscosities are approximately 250 and 40 sec at 30 and 100 deg C, respectively. Compound *B* is a paraffin base cylinder oil having a Saybolt viscosity of 150 sec at 100 deg C. Compound *C* is of a petrolatum base containing a small amount of rosin (about 5 per cent). The Saybolt viscosity-second characteristics of all three compounds are given in Fig. 3 of bibliography reference No. 2.

All measurements were made on the mutual-inductance power-factor bridge which has been in use in The Harvard Engineering School laboratories for some years past.[3]

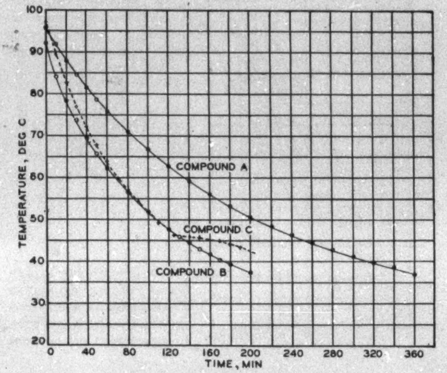

FIG. 1—COOLING CURVES OF THE THREE INSULATING COMPOUNDS TESTED

## COOLING CURVES

It has been found that when compounds are heated to 100 deg C or thereabouts and allowed to cool slowly, the temperature-time characteristic frequently shows an abrupt change, usually near 50 deg C. Moreover, the electrical characteristics of many cable papers impregnated with compounds show abrupt changes or reach minima at or near this temperature. For example, the minimum of the V- or U-curves occur at or near this temperature. (See Figs. 14, 15, and 16 in bibliography reference No. 1; Figs. 4 and 6 in No. 5; pp. 38-46 in No.

9; also Nos. 11 and 12.) Possibly this change in slope is due to a change in the molecular structure of the compound which is accompanied by an internal thermal change. Cooling curves for these three compounds are given in Fig. 1. It may be noted that compounds *A* and *B* show no abrupt changes in slope; compound *C* shows such a change at 46 deg C. This may be due to a molecular change in the rosin itself or to an interaction of the rosin content with other ingredients of the compound at this temperature.

## POWER LOSS-VOLTAGE GRADIENT CHARACTERISTICS

As a rule, at room temperature, the power factor and dielectric constant of impregnated paper as functions of voltage gradient are constant.[2] This relationship has been found also by others.[4] Furthermore, in the Harvard laboratories, this relationship has been found true with pyrex and other glasses which are much more nearly perfect dielectrics than impregnated cable papers. When the power factor and dielectric constant do not vary with change in voltage gradient, the power loss must increase as the square of the voltage gradient. When the power loss varies as the square of the voltage gradient, the power loss-voltage gradient characteristics when plotted with log-log coordinates are linear and have a geometrical slope of 2. Such characteristics for compounds *B* and *C* are given in Figs. 2 and 3. In each case the slope of the graph at room temperature (about 20 deg C) is 2. Hence, at room temperature, the power loss in cable impregnating compounds *usually increases as the square of the voltage gradient.*

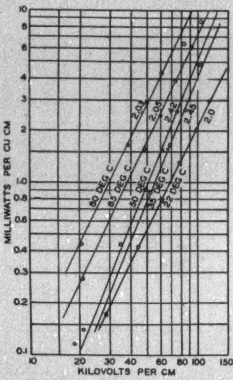

FIG. 2—(LEFT) POWER LOSS - VOLTAGE GRADIENT CHARACTERISTICS OF COMPOUND *B*, PLOTTED WITH LOGARITHMIC COORDINATES

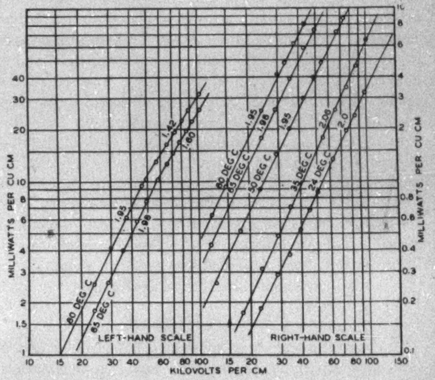

FIG. 3—(RIGHT) POWER LOSS - VOLTAGE GRADIENT CHARACTERISTICS OF COMPOUND *C*, PLOTTED WITH LOGARITHMIC COORDINATES

With the exception of the graphs at 65 and 80 deg C for compound *C*, the logarithmic power graph for each of these three compounds is a single straight line at every temperature; at these two temperatures, for compound *C*, each graph consists of two straight lines. Compound *C* contained rosin; it is well known that at temperatures at and above 65 deg C some of the constituents of rosin (abetic acid) volatilize and changes occur in its composition. This effect has been reported also by Whitehead (p. 57 in reference No. 10). The change in slope of these two graphs is undoubtedly due to some change in the rosin content of the compound. It is to be noted, however, that both sections of each graph are linear.

The foregoing graphs indicate that among cable impregnating compounds there is a tendency for the power loss to increase as a constant power of the voltage gradient. This exponential law has been observed by others.[11] Even at the two higher temperatures for compound *C* this law appears to hold. The constants of the functions at the higher values of voltage gradient, however, differ from those at the lower gradients.

The slopes ($\alpha$ in Table I) do not appear to have any definite relationship to the temperature. Above room temperature, slopes of less than 2.0 seem to predominate for compounds *A* and *C*, whereas the slopes for compound *B* are all greater than 2.0. When the slope is less than 2 the power factor decreases with increase in voltage gradient (see eq (4)). Whitehead, Kouwenhoven, and Hamburger[4] explain this phenomenon as follows: With the best impregnated paper, *i.e.*, absence of moisture, the ions become more mobile at the higher temperatures and accordingly are swept out of the field more rapidly by the increasing voltage gradients. Dunsheath[14] explains a rising power factor characteristic as being due to inevitable particles of moisture becoming more elongated under increasing voltage gradient.

From the foregoing relationships, it follows that the power loss per unit volume is

$$P = KE^{\alpha} \text{ watts per cu cm} \qquad (1)$$

where *K* is the loss coefficient, *E* the voltage gradient in volts per cm, and $\alpha$ the loss exponent. In Table I are given the values of $K$ and $\alpha$ for the three compounds, $A$, $B$ and $C$.

TABLE I

| Compound | Temperature deg C | $\alpha$ | $K$ (multiply by $10^{-13}$) |
|---|---|---|---|
| | 19.5 | 2.0 | 1.718 |
| | 35.0 | 2.15 | 0.915 |
| *A* | 50.0 | 1.9 | 18.9 |
| | 65.0 | 1.84 | 55.9 |

| | 65.0† | 1.60 | 2,490.0 |
| | 80.0‡ | 1.95 | 73.5 |
| | 80.0§ | 1.42 | 23,800. |

*$E$ less than 66 kv per cm
†$E$ greater than 66 kv per cm
‡$E$ less than 64 kv per cm
§$E$ greater than 64 kv per cm

The foregoing power loss-voltage gradient characteristics are not unique properties of carefully prepared impregnated paper samples only. In Fig. 4 are shown the power loss-voltage gradient characteristics of a 10-ft sample of a 300,000-cir mil 6/32-in. (0.477-cm) wall impregnated-paper cable for several different temperatures. There are two sets of characteristics: one set was obtained before the cable had been subjected to any life test; the second set was obtained after this cable had been subjected to 190.7-hr life test, the temperature undergoing a weekly cyclic variation of from 20 to 60 deg C and the voltage undergoing a weekly cyclic variation of from 0 to 42.5 kv. Under these conditions this cable showed only very slight ionization. It is to be noted that in every case these characteristics are linear, indicating again that under these conditions the power loss varies as a constant power of the voltage gradient. Such characteristics are typical of many impregnated paper cables having no appreciable ionization.

It is believed that the coefficient $K$ and the exponent $\alpha$ may be used as a basis for the comparison of cable-impregnating compounds.

## POWER FACTOR CHARACTERISTICS

Equation (1) makes it possible to express the power factor of an impregnating compound in analytical form. Thus the power factor is given by

$$\text{Power factor} = \frac{P}{EI} = \frac{P}{E^2C\omega} = \frac{KE^\alpha}{E^2C\omega} \qquad (2)$$

where $C$ is the capacitance in farads per cu cm and $\omega$ is $2\pi$ times the frequency $f$.

From equation (2),

$$\text{Power factor} = \frac{KE^{\alpha-2}}{C\omega} \qquad (3)$$

It was found that the maximum variation of the capacitance $C$ at any one temperature was 4 per cent for all three compounds. This was an extreme value occurring at 50 deg C for compound $C$. For the most part, the variation was of the order of 1.5 per cent.

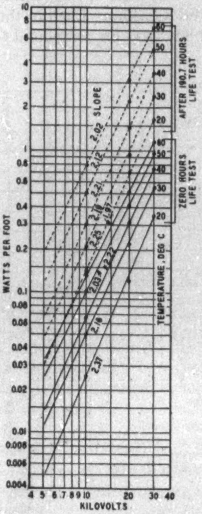

FIG. 4—(LEFT) POWER LOSS - VOLTAGE GRADIENT CHARACTERISTICS OF 300,000-CIR-MIL CABLE WITH 6/32-IN. IMPREGNATED PAPER INSULATION

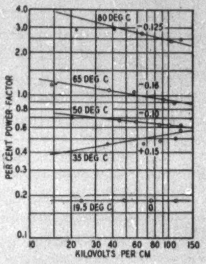
FIG. 5—(BELOW) POWER FACTOR CHARACTERISTICS OF COMPOUND *A* PLOTTED WITH LOGARITHMIC COORDINATES



If an average value be used, at the most the change in the capacitance $C$ is only 2 per cent. Hence, for practical purposes

$$\text{Power factor} = K_pE^{\alpha-2} \qquad (4)$$

where $K_p$ is essentially a constant and equal to $K/C\omega$.

If the power factor characteristic be plotted with log-log coordinates, the resulting graph should be linear and the geometrical slope should be $\alpha - 2$. It is apparent that if $\alpha = 2$, the slope is zero and the characteristic is a horizontal straight line, such as occurs at room temperatures. If $\alpha > 2$, the slope is positive; if $\alpha < 2$, the slope is negative.

As an example, the log-log power factor characteristics for compound $A$ are shown in Fig. 5 and the slope of each characteristic is designated thereon. These characteristics are all linear. The slopes $(\alpha - 2)$ are very nearly in accordance with the values of $\alpha$ given in Table I.

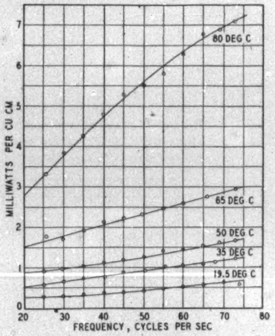
With each of the three compounds, the slopes of the power-factor characteristics for room temperature are all found to be zero in accordance with the foregoing analysis. With both compounds *A* and *C*, the slopes of the characteristics are both positive and negative.

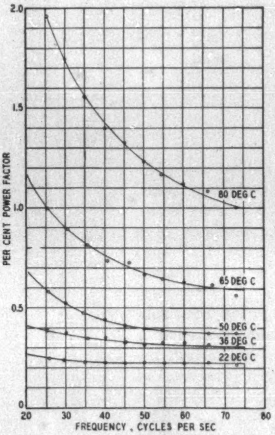
When the power factor characteristics are plotted on the usual coordinate paper, as a rule they are not exactly linear, but with the usual scales used they are nearly so. However, it is well known that their slopes are sometimes found to be positive and sometimes negative. Whether or not their slopes are positive or negative also depends on whether $\alpha$ is greater or less than 2. Frigon[11] also shows this last relationship. Each of the two characteristics at 65 and 80 deg C for compound *C* is found to have two slopes, which is in accordance with the changes in slope of the power characteristics in Fig. 3.

It may be observed that with a few of the characteristics, the relation of the plotted points to the characteristics indicates poor precision. This is due to the fact that the slopes are the differences of two nearly equal quantities $\alpha$ and 2 and hence the differences usually are very small, relatively to $\alpha$ and 2. As an extreme example, in Fig. 2 consider the characteristic at 80 deg C where $\alpha = 2.03$. An error of only 1 per cent in the value of $\alpha$ produces an error of 600 per cent in the slope of the power factor characteristic. Hence, these power factor characteristics are sensitive criteria of precision and the values of $\alpha$ in equation (1) may be obtained from them with much greater precision than from the power characteristics themselves.

## POWER-FREQUENCY CHARACTERISTICS

In electrical measurements over the limited ranges of power frequencies made with many different dielectrics, the authors have always found that if the dielectric was homogeneous, the power loss at constant temperature and frequency varied almost as a linear function of the frequency. This relationship has been found to hold with such high grade dielectrics as glass and pyrex,[6] with carefully impregnated paper insulation such as with the three compounds, *A*, *B*, and *C*, and even with cables which have negligible ionization. Frigon[11] in his tests of impregnated papers also shows this same relationship. (The authors realize that this linear relationship does not exist over extremely wide ranges of frequency because of the Debye dipole effect.[7,13])





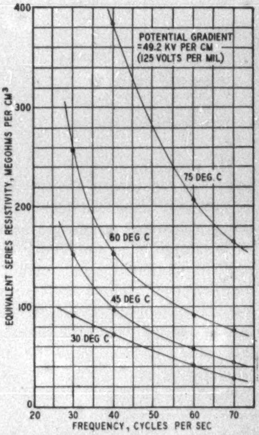


FIG. 6—(ABOVE) POWER LOSS-FREQUENCY CHARACTERISTICS FOR COMPOUND *A*

FIG. 7—(CENTER) POWER FACTOR-FREQUENCY CHARACTERISTICS FOR COMPOUND *B*

FIG. 8—(RIGHT) SERIES RESISTIVITY-FREQUENCY CHARACTERISTICS FOR COMPOUND *A*

The power-frequency characteristics for compound *A* at constant voltage gradient of 49.2 kv per cm (125 volts per mil) and for various temperatures, are given in Fig. 6; they are typical of those for the other two compounds. These characteristics are linear, except that the characteristic at 80 deg C shows very slight curvature. For most practical purposes, however, the linear relationship may be assumed and the power expressed by the equation

$$P = P_0 + mf \text{ watts per cu cm} \qquad (5)$$

where $P_0$ is the intercept of any characteristic with the power axis, $m$ is the slope of the characteristic and $f$ the frequency. Obviously $P_0$ is the inferred power loss per cu cm at zero frequency or with direct current.

In Table II are given the frequency constants $P_0$ and $m$ of the three compounds for different temperatures.

TABLE II

| Compound | Temperature deg C | $P_0$† | $m$† |
|---|---|---|---|
|  | 19.5 | 0.1 | 0.0075 |
|  | 35 | 0.25 | 0.017 |
| *A* | 50 | 0.55 | 0.0094 |
|  | 65 | 1.0 | 0.026 |
|  | 80 | 1.2* | 0.086* |
|  | 22 | 0.04 | 0.0075 |
|  | 36 | 0.14 | 0.018 |
| *B* | 50 | 0.36 | 0.009 |
|  | 65 | 0.66* | 0.0146* |
|  | 80 | 1.63 | 0.0201 |
|  | 24 | 0.15 | 0.0091 |
| *C* | 42 | 0.05 | 0.025 |
|  | 60 | 2.3 | 0.032 |
|  | 80 | 2.3 | 0.0725 |

*Up to about 60 or 65 cycles.

†Multiply all values by $10^{-3}$.

## POWER FACTOR-FREQUENCY CHARACTERISTICS

From equation (5), it may be shown that the power factor-frequency characteristics for such compounds are essentially rectangular hyperbolas.

For example, the power factor

$$\text{Power factor} = \frac{P}{E^2C\omega} = \frac{P_0 + mf}{E^2C(2\pi f)}$$

$$= \frac{P_0}{2\pi E^2Cf} + \frac{m}{2\pi E^2C} = \frac{a}{f} + b \qquad (6)$$

where $a$ and $b$ are essentially constant.

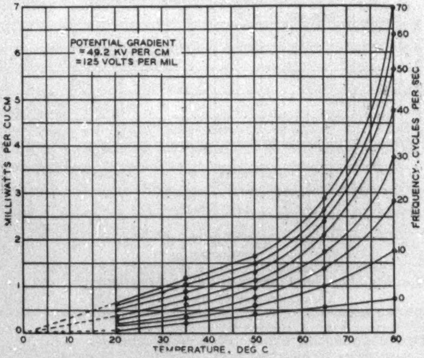

FIG. 9—POWER LOSS-TEMPERATURE CHARACTERISTICS FOR COMPOUND *A* AT DIFFERENT FREQUENCIES

The first term of equation (6) is the well-known equation of the rectangular hyperbola; the second term is constant. Hence, equation (6) represents a rectangular hyperbola in the first quadrant with the power axis as one asymptote and a line parallel to the frequency axis, + $b$ watts from it, as the other asymptote. Fig. 7 gives the power factor-frequency characteristics for compound $B$ at a constant voltage gradient of 49.2 kv per cm, (125 volts per mil) for different temperatures. It may be observed that these characteristics are rectangular hyperbolas in accordance with equation (6). (Corresponding characteristics for compounds $A$ and $C$ are very similar.) Frigon[11] shows this same type of characteristic, but does not attempt to derive the functions.

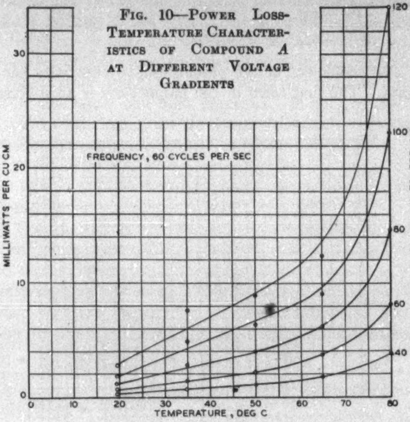

FIG. 10—POWER LOSS-TEMPERATURE CHARACTERISTICS OF COMPOUND *A* AT DIFFERENT VOLTAGE GRADIENTS

From equation (6) the power factor approaches $b$, or $m/(2\pi E^2C)$, as the frequency is increased, provided the dipole molecular effect does not occur. With compound $B$ at 65 deg C, $a = 0.1635$ and $b = 0.00363$. At a frequency of 50 cycles, the power factor is equal to $0.00327 + 0.00363 = 0.00690$.

Hence, at this temperature and frequency, the two terms in equation (6) are almost equal.

## EQUIVALENT SERIES RESISTIVITY

The equivalent series resistivity is

$$\rho = \frac{P}{I^2} = \frac{P}{E^2C^2\omega^2} \qquad (7)$$

When it is desired that $\rho$ become a function of the voltage gradient $E$, at constant temperature and frequency, equation (1) may be substituted in equation (7) giving

$$\rho = \frac{KE^{\alpha}}{E^2C^2\omega^2} = \frac{K}{C^2\omega^2}E^{\alpha - 2} \qquad (8)$$

Since $C$ is essentially constant for any given temperature and over the usual ranges of voltage gradient, equation (8) is the same form of function as the power factor characteristic. It is generally true that the equivalent series resistivity and the power factor characteristic are similar in form as already has been shown by one of the authors.[8]

When $\rho$ becomes a function of temperature, at constant frequency and voltage gradient, the function is essentially that of the power-temperature characteristic. When $\rho$ becomes a function of frequency, at constant voltage gradient and temperature, the function is a combination of a rectangular hyperbola and an inverse square function. For example, from equations (5) and (7)

$$\rho = \frac{P_0 + mf}{E^2C^2(2\pi f)^2} = \frac{1}{(2\pi EC)^2}\left(\frac{P_0}{f^2} + \frac{m}{f}\right) \quad (9)$$

The coefficient of the parenthesis is essentially constant. The first term in the parenthesis is an inverse square term and the second term used alone gives the equation of a rectangular hyperbola. Hence, the equivalent series resistivity characteristic is the sum of an inverse square function and a rectangular hyperbola. A family of these characteristics for compound $A$ is shown in Fig. 8.

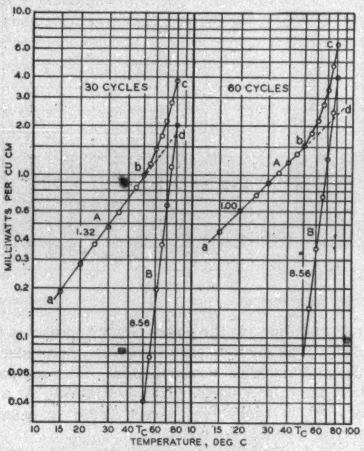

FIG. 11—POWER LOSS-TEMPERATURE CHARACTERISTICS OF COMPOUND *A*, PLOTTED WITH LOGARITHMIC COORDINATES

## EQUIVALENT PARALLEL CONDUCTIVITY

The equivalent parallel conductivity is

$$\gamma_p = \frac{P}{E^2} = \frac{KE^{\alpha}}{E^2} = KE^{\alpha - 2} \quad (10)$$

Hence, the equivalent parallel conductivity function is of the same form as the power factor function given in equation (4).[8] From equation (5), $\gamma_p$ as a function of frequency, with constant temperature and voltage gradient, is linear being similar to the power-frequency function.

## POWER-TEMPERATURE CHARACTERISTICS

It was found possible to resolve the power-temperature characteristics into two simple exponential components. This analysis is found to be valid for the family of characteristics plotted with constant voltage gradient, but with different values of frequency (Fig. 9). Except for the very lowest portions of the characteristics for compound $C$, the analysis is valid for the family of characteristics plotted with constant frequency and with different values of voltage gradient (Fig. 10).

Consider Fig. 11, which gives the power-temperature characteristics *abc* at both 30 and 60 cycles for compound $A$ (from Fig. 10) plotted with log-log coordinates. Up to 50 deg C each characteristic is linear, showing that up to this temperature the power increases as a constant power of the temperature. At 50 deg C, the upper portion *bc* of the graph departs from the lower linear portion *ab* and lies above *bd*, the lower linear portion extended. At temperature $T_c$, corresponding to point *b*, the characteristic departs from the simple initial exponential law. However, if the portion *bd* be subtracted from the portion *bc* and replotted on log-log coordinates, as shown by characteristic $B$, the resulting graph also is found to be linear. Thus, beyond the critical temperature $T_c$, the power is represented by the sum of two exponential characteristics $A$ and $B$. The geometrical slope and hence the exponent of the function is denoted on each characteristic. The characteristics shown in Fig. 11 are re-plotted in Cartesian coordinates in Fig. 12.

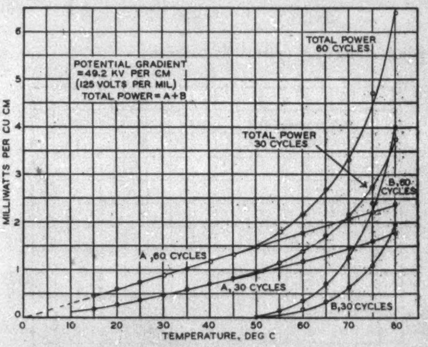

FIG. 12—COMPONENTS OF POWER LOSS-TEMPERATURE CHARACTERISTICS OF COMPOUND *A*

The total power $P$ may be expressed as the sum of two components

$$P = A + B \quad \textbf{(11a)}$$

$$= aT^n + bT^p \quad \textbf{(11b)}$$

where $a$ and $b$ are coefficients and $n$ and $p$ are exponents, all constant at any one frequency and voltage gradient;

the second terms are zero below the critical temperature $T_c$. The exponent *n* is of the order of unity and decreases with increase in frequency. The constant *a*, when used in connection with watts per cubic centimeter, varies from nearly zero at 20 cycles to the order of 0.05 to 0.1 at 70 cycles for compounds *A* and *B*; for compound *C*, *n* is of the order of from 2 to 4 and *a* varies from zero to 8 x $10^{-4}$. The variation of these two constants with frequency for all three compounds is shown in Fig. 13.

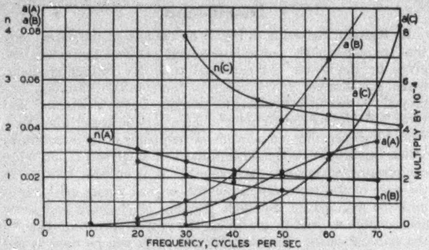

FIG. 13—VALUES OF *a* AND *n* OF EQUATION (**11b**) FOR ALL THREE COMPOUNDS

For compound *C* at the lower frequencies, the component *B* becomes negative. In Fig. 14 are shown three log-log power-temperature characteristics of compound *C* for 60, 45, and 30 cycles at a constant voltage gradient of 49.2 kv per cm (125 volts per mil). It may be noted that at 60 cycles the portion *bc* of the characteristic lies above the straight line *abd*; at 45 cycles there is no deviation from a straight line relationship, showing that the *B* component is zero at all temperatures; at 30 cycles the portion *bc* of the characteristic lies below the straight line *abd*, showing that the *B* component of the power characteristic is negative. However, at both 60 and 30 cycles the *B* component of the power loss still follows the simple exponential law, as is shown by the characteristic *B* for both these frequencies.

The values of the constants *b* and *p* for the three compounds are given in Table III.

TABLE III—CONSTANTS *b* AND *p* IN EQUATION (11b)

| Frequency cycles per sec | Compound *A* | | Compound *B* | | Compound *C* | |
|---|---|---|---|---|---|---|
| | *b* | *p* | *b* | *p* | *b* | *p* |
| 75 | | | | | 0.542x$10^{-9}$ | 5.08 |
| 70 | 0.222x$10^{-15}$ | 8.56 | 0.096x$10^{-12}$ | 7.0 | | |
| 60 | 0.198x$10^{-15}$ | 8.56 | 9.89 x$10^{-12}$ | 5.88 | 0.704x$10^{-8}$ | 4.38 |
| 50 | 0.198x$10^{-15}$ | 8.56 | 4.95 x$10^{-12}$ | 6.04 | | |
| 40 | 24.07 x$10^{-15}$ | 7.40 | 0.425x$10^{-12}$ | 6.54 | | |
| 30 | 0.103x$10^{-15}$ | 8.56 | 0.211x$10^{-16}$ | 8.84 | 0.502x$10^{-15}$ | 8.50 |
| 20 | 13.58 x$10^{-15}$ | 7.32 | | | | |
| 10 | 0.019x$10^{-15}$ | 8.60 | | | | |

It is interesting to note that Frigon[11] also expressed portions of his power-temperature characteristic as two logarithmic functions. However, his characteristics were of the U or V type. He gives the power *P* as follows:

$$\text{From } 0 \text{ deg C to } 25 \text{ deg C} \quad P = mT^{-0.3}$$
$$70 \text{ deg C to } 110 \text{ deg C} \quad P = oT^{3.6}$$

where *P* is power, *m* and *o* constants, and *T* temperature in deg C.

The first term applies to the portion of the characteristic at the left of the minimum and the second term to the portion at the right of the minimum. It is also interesting to note the similarity of the content and analyses of this paper to those of Frigon, although the Frigon paper was not discovered by the authors until after this paper had been prepared. It may be noted further that none of the three samples described in this paper shows any tendency toward the well known U or V power or power factor characteristics. This may well be due in part to the dielectric characteristics of the paper itself.

The analysis of the power loss in these compounds into two exponential components appears at this time to be only empirical. However, two factors seem to have some significance: First, the critical change occurs at or very near 50 deg C; other investigators have found this temperature to be critical in relation to the electrical characteristics of compounds of this character. Second, the power losses, whether functions of voltage gradient or of temperature, have a tendency to follow an exponential law. It is well known that ionization currents in gases, for example, such as are given by Townsend's continuity theorem, are exponential in character. Hence, it may be shown at some later time that the foregoing relationships are due to inherent characteristics of the molecular relationships within the dielectric.

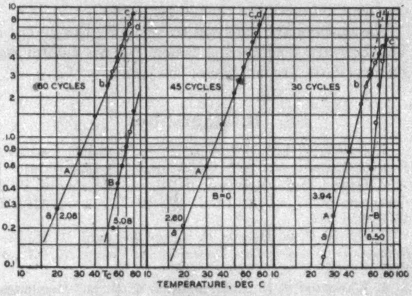

FIG. 14—POWER LOSS-TEMPERATURE CHARACTERISTICS OF COMPOUND *C* FOR THREE DIFFERENT FREQUENCIES, PLOTTED WITH LOGARITHMIC COORDINATES

**Potential gradient, 49.2 kv per cm (125 volts per mil)**

## CONCLUSIONS

1. An abrupt change in the slope of the cooling curves of some cable compounds occurs in the neighborhood of 50 deg C; this may indicate changes in the molecular structure.

2. It appears to be a general law that the power loss in cable compounds varies as a constant exponential power of the voltage gradient, the exponent usually being 2 at room temperature; at higher temperatures it may be greater or less than 2.

3. The power factor characteristics of cable compounds are exponential functions of the voltage gradient, the exponent being related to that for the power characteristics.

4. The power-frequency characteristics are essentially linear, having a positive intercept at zero frequency.

5. The power factor-frequency characteristics are essentially rectangular hyperbolas.

6. The equivalent series resistivity-voltage gradient characteristic is the same type of function as the power factor-voltage gradient characteristic.

7. The equivalent parallel conductivity-voltage gradient characteristic is the same type of function as the power factor-voltage gradient characteristic.

8. The power-temperature characteristics for constant frequency and constant voltage gradient appear to consist of two terms, each of which is a constant-exponential function of the temperature.

The authors are indebted to Dean H. E. Clifford of The Harvard Engineering School for his helpful suggestions in the preparation of this paper.

## Discussion

**R. Reiter:** Referring to Fig. 2, or Table I, of the paper, note that the slopes of the power loss-voltage gradient characteristics, given by the power loss exponent $\alpha$ of the voltage gradient, reach a maximum in the range of temperature variation employed. Other investigators, for example Debye*, Kitchin,* and Race, have found similar critical characteristic peaks when they varied the operating temperature or frequency of their materials, which consisted of single chemicals such as glycerin, and more complicated compounds such as oils. It is possible that, as in the case of the turbo-alternator set, critical points exist which must be avoided by the cable designer in choosing and using cable materials, and in specifying the proper operating range of the finished cable. Professor Dawes' work can be used to advantage in determining the proper design constants and thus can reduce materially the factor of ignorance which is now known to be high.

**Eric A. Walker:** The writer recently has been conducting numerous tests at the Harvard Engineering School, to determine the relationship between the electrical characteristics of cables and the frequency. It was found that the power loss in impregnated paper insulated cables was given by the function.

$$P = P_0 + mf^{\alpha} \tag{1}$$

where

$P$ is the a-c power loss in watts per 1,000 ft.

$P_0$ is the d-c power loss in watts per 1,000 ft.

$m$ is a constant for any one voltage and temperature.

$f$ is the frequency in cycles per second.

$\alpha$ is a constant exponent for any one voltage and temperature.

Then the

$$\text{power factor} = \frac{P_0}{Kf} + \frac{m}{Kf^{1-\alpha}} \tag{2}$$

where $K = 2\pi E^2 C$

$E$ being the impressed rms voltage.

$C$ the capacitance in farads.

If $\alpha$ = unity these equations are identical to those given by Professor Dawes, and equation (2) represents a rectangular hyperbola with one asymptote displaced from the frequency axis by a constant quantity.

$P_0$ was measured accurately by applying a high continuous voltage and measuring the steady-state leakage current. The power loss $P$ with alternating voltage was measured with a Dawes-Hoover bridge.

For a 350,000 cir-mil stranded conductor cable with 19/64 inch (7.52 mm) wall impregnated paper insulation, at 13,950 volts and room temperature, $P_0$ was found to be 0.0014 watt per 1,000 ft and $P$ at 60 cycles per second was 24.2 watts per 1,000 ft.

However, as is shown in Fig. 1, curve $A$, $\alpha$ was not equal to unity but equal to 0.965. By inspecting equation (2) it is seen that the power factor-frequency characteristic is not a rectangular hyperbola but is a characteristic which rises more rapidly than a rectangular hyperbola as the frequency decreases. This function is shown in Fig. 2.

---

*This work is described in Gemant's "Electrophysik der Isolierstoffe."

It is evident also that if $\alpha$ were greater than unity the power factor might decrease as the frequency is decreased, for then we have

$$\text{power factor} = \frac{P_0}{Kf} + mf^{\alpha-1} \qquad (3)$$

as is shown from the d-c measurements $mf^{\alpha}$ greatly exceeds $P_0$ and as $mf^{\alpha-1}$ will decrease with frequency for values of $\alpha$ from 1 to 2, the power factor also may decrease.

The equivalent series resistance as determined by Professor Dawes is given by:

$$\rho = \frac{P}{K'f^2} = \frac{P_0}{K'f^2} + \frac{m}{K'f^{2-\alpha}} \qquad (4)$$

where $K' = (2\pi EC)^2$

If, as has been shown $P_0$ is negligible compared with $mf^{\alpha}$, and $\alpha$ equals unity the equation represents a rectangular hyperbola. However as $\alpha$ in the cable under discussion equals 0.965 the characteristic rises more rapidly than a rectangular hyperbola as the frequency is decreased. In Fig. 2 the equivalent series resistance characteristic for this cable rises more rapidly than a rectangular hyperbola.

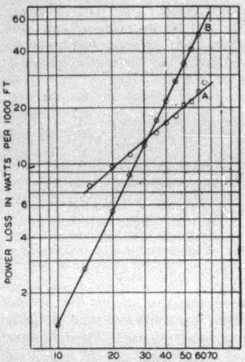

Fig. 1—Power Loss *vs* Frequency

Curve A—350,000-cir mil stranded conductor 19/64 in. wall impregnated paper insulation—13,950 volts, 20 deg 5 C

Curve B—No. 6 solid conductor 7/32 in. wall rubber insulation—7,000 volts, 20 deg 5 C

Very different characteristics were obtained when rubber-insulated cables were tested. For a No. 6 solid copper conductor, 7/32 inch (5.55 mm) wall rubber insulation at room temperature and 7,000 volts the power factor is a linear function of frequency from 10 to 60 cycles per sec. The characteristic for frequencies from 10 to 60 cycles is given in Fig. 3. By extrapolation the power factor at zero frequency becomes zero. This seems anomalous for under continuous voltage conditions, after the transient has subsided, the power factor equals unity. However the definition of the power factor as the cosine of the angle between the voltage and current loses its significance with continuous voltage.

The equivalent series resistance and the equivalent series capacitance remain constant with change of frequency.

With an equivalent series circuit to represent the dielectric:

$$\text{power} = \frac{KE^2\,(\text{power factor})^2}{\text{equivalent series resistance}} \qquad (4)$$

Therefore the power should be an exponential function of frequency. This is shown by curve *B* in Fig. 1 where power is plotted as a function of frequency on log-log coordinate paper. The slope of the characteristic is 2. Therefore for this rubber insulated cable

$$P = P_0 + bf^2$$

where $P_0$ at 7,000 volts and room temperature = 0.0077 watts/1,000 ft and is negligible above 10 cycles per second; $b$ is a constant and is equal to $2.83 \cdot 10^{-10}E^2$.

**J. B. Whitehead:** Most of the behavior shown for impregnated paper by Messrs. Dawes and Humphries can be accounted for in terms of the theory of dielectric absorption. Under this theory power loss increases as the square of the voltage gradient. At higher temperatures the increase in the conductivity of the oil causes a more rapid rise with voltage. At low temperatures power factor is independent of the voltage gradient and either may rise or fall at higher temperatures, depending on the initial conductivity or ionic content of the oil. Power loss is proportional to frequency, but also proportional to power factor, and the latter either may rise or fall with frequency. Consequently, the power frequency relationship is not simple. In the writer's

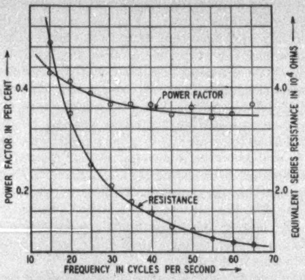

Fig. 2—Power Factor and Equivalent Series Resistance *vs* Frequency

350,000-cir mil stranded conductor 19/64 in. impregnated paper insulation—13,950 volts, 20 deg 5 C

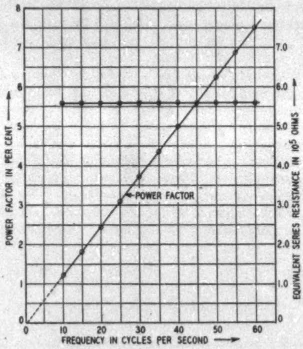

Fig. 3—Power Factor and Equivalent Series Resistance *vs* Frequency

No. 6 solid conductor—7/32 in. wall rubber insulation—7,000 volts, 20 deg 5 C opinion, the power factor frequency curve is not a hyperbola, but the curves as the authors have shown them, if extended to lower frequencies, would pass through a maximum decreasing to zero at zero frequency. A number of variations in the shape of the loss temperature curve of impregnated paper, as affected by the characteristics of the oil, may be seen in the paper, *The Dielectric Losses in Impregnated Paper*, A.I.E.E. TRANS., June 1933, p. 667.

**C. L. Dawes:** Mr. Walker finds that with a commercial impregnated paper cable the alternating current component of power loss does not increase proportionately to the frequency as was found by the authors for carefully impregnated flat samples, but rather to the 0.965 power. The two exponents differ from each other only by 3.5 per cent which is not large when the wide variations among the properties of even similar dielectrics are considered. The difference cannot be attributed to errors in measurement since the precision was far too high to permit a deviation of 3.5 per cent. It can be shown theoretically that with homogeneous insulation the power loss as a function of frequency should be the same whether the sample is flat or cylindrical. As is well known a somewhat similar discrepancy exists between the actual dielectric strength of homogeneous cylindrical dielectrics, and that derived theoretically from the properties of flat samples. Mr. Walker who is conducting this research at the Harvard Engineering School continually is obtaining new data and eventually it may become possible for him to reconcile this difference in the exponents.

It is this same difference in the exponents which accounts for the power factor and equivalent series resistance relationships which he derives from his equations (3) and (4).

Mr. Walker is obtaining some very interesting results with rubber cables when subjected to relatively high voltage gradients. The alternating current component of power loss appears to increase as the square of the frequency rather than as the first power as is found with impregnated paper. This relationship is quite surprising. Mr. Walker intends to investigate this phenomenon further and undoubtedly will conduct power frequency experiments with flat rubber samples for comparison.

Doctor Whitehead states that at the higher temperatures the increase in the conductivity of the oil causes a more rapid rise of loss with the voltage gradient than at the lower temperatures. From his previous sentence which refers to the square of the voltage gradient it might be inferred that at the higher temperatures the loss increased at a higher power of the voltage gradient than the squared power. That this is not true is shown in Table I. For example, with compound *A* the value of the exponent $\alpha$ at 19.5 deg C is 2.0 whereas at 80 deg C it is but 1.875. Likewise the exponent for compound *C* at the higher temperatures is considerably less than at room temperature. The exponent for compound *B* reaches a maximum of 2.4 at 50 deg C and is only 2.03 at 80 deg C. Similar relationships occur with the 300,000 cir mil cable whose characteristics are shown in Fig. 4. Hence the more rapid rise of loss with voltage gradient at the higher temperatures to which Doctor Whitehead calls attention and which undoubtedly is due in a large measure to an increase in the conductivity of the oil obviously is not given by an increase in the voltage gradient exponent. Further inspection of Table I shows however that the coefficient *K* increases very rapidly with temperature. For example, with compound *A* the value of *K* at 80 deg C is 98.5 compared with 1.718 at 19.5 deg C. Thus the more rapid increase in loss with voltage gradient at the higher temperatures is accounted for by an increase in the power loss coefficient and not in the voltage gradient exponent.

Doctor Whitehead's statement that power loss is proportional to power factor obviously is correct, but in attempting to analyze the properties of dielectrics we find it more simple to consider power loss as a fundamental property of the dielectric rather than the power factor. The power factor is a function of two properties, power loss and voltamperes, and the voltamperes in turn are proportional to the permittivity. The permittivity obviously is a fundamental property of the dielectric. Hence to us it appears more rational to consider power loss rather than power factor as a fundamental criterion of dielectric properties.

It may well be, as Doctor Whitehead states, that the power factor frequency characteristics are not rectangular hyperbolas to frequencies at or very near zero since the power factor may be zero at zero frequency. We of course find the characteristics to be rectangular hyperbolas in the frequency range of from 75 to 20 cycles. The region between zero frequency and the very low power frequencies is practically unexplored. The experimental difficulties in extending the frequency below 15 cycles are well known. To us it would seem that the characteristics would remain rectangular hyperbolas at least to frequencies that were almost zero. Possibly near zero frequency a maximum might be reached and the power factor fall very rapidly to zero, thus giving a discontinuity in the slope of the characteristic at or near zero frequency. However, so far as we know this fact has not been confirmed experimentally. Mr. Walker states that with rubber cables the power factor function does give zero power factor at zero frequency. Our knowledge of the fundamental properties of dielectrics would be increased considerably were data on the properties of dielectrics between zero frequency and 15 cycles available, particularly data near zero frequency. The difficulties of making these measurements may be overcome at some time in the near future if the recent progress in making dielectric loss measurements continues.

# Loss Characteristics of Silicon Steel at 60 Cycles with D-C Excitation

BY R. F. EDGAR*
Associate, A.I.E.E.

INTEREST in the loss characteristics of sheet steel subjected to combined alternating and direct magnetic fields is of long standing. Previous work on the subject includes that reported by M. Rosenbaum[1] and F. Holm[2] in 1912, by J. D. Ball[3], and L. W. Chubb and Thomas Spooner [4,5] in 1915 and '21, and by Y. Niwa, Y. Asami[6], J. Matura, and J. Sugiura[7] in 1923 and '24. (For numbered references see Bibliography.)

FIG. 1—WAVE FORMS OF INDUCED VOLTAGE, FLUX DENSITY, AND EXCITING CURRENT WITH CORRESPONDING HYSTERESIS LOOPS, SHOWING THE EFFECT OF D-C EXCITATION

$a$—Alternating flux density (one-half total pulsation)
$d$—Direct flux density (average over a complete cycle)
$p$—Peak flux density (maximum in each cycle)
$x$—Amplitude of exciting-current pulsation
$y$—Direct component of exciting current (average current)
$z$—Peak value of exciting current
Subscript 1 refers to conditions with no d-c excitation
Subscript 2 refers to conditions with d-c excitation

There are a number of applications in which either power transformers or instrument transformers may be subjected to d-c excitation. The a-c core-loss and excitation characteristics of the core material under such conditions are of importance, for they affect the rating of the power transformers and the accuracy of the instrument transformers. Combined alternating and direct magnetic fields are present in other types of apparatus also, affecting their performance by changing the characteristics of the magnetic circuits.

The diagrams of Fig. 1 illustrate the change of the cycle of magnetization which is caused by a direct component of exciting current. The flux wave and the corresponding hysteresis loop are shifted from their symmetrical positions by a direct component of flux density. The shape of the hysteresis loop is changed; in general, its area, which represents the hysteresis loss per cycle, also is changed, although the amplitude of pulsation (vertical length) remains the same.

The eddy current loss, being a function of the effective value of the induced voltage, is not affected by the direct component of flux density, if, as assumed in Fig. 1, the amplitude and form of the flux and voltage waves remain unchanged. The assumption regarding the form of the voltage wave is only approximately correct, however. Changes in the exciting current wave form and amplitude will react upon the impedance in the magnetizing circuit to distort the wave form of the induced voltage; so that the eddy current loss will be changed somewhat.

The change in the exciting current is associated with the change in the shape of the hysteresis loop. The general slope of the loop is decreased, so that the same pulsation of flux density (vertical length) requires a much greater pulsation of exciting current (horizontal length). Thus, in Fig. 1, the amplitude of the exciting current pulsation ($x_2$, $x_1$) is much greater for the displaced than for the symmetrical flux wave, although the amplitude of flux pulsation ($a_2$, $a_1$) is the same for both. There is, of course, a small component of exciting current due to eddy current loss, which is neglected in Fig. 1.

The converse effect, that of superposed a-c excitation on the d-c excitation is illustrated by the diagrams of Fig. 2. The two flux waves have the same direct components of flux density ($d_1$, $d_2$) but different alternating components ($a_1$, $a_2$). The direct components of exciting current ($y_1$, $y_2$) are quite different.

The changes in the shape of the hysteresis loop illustrated in Figs. 1 and 2, have been shown in detail by several of the investigators mentioned previously. This paper describes a series of a-c core loss and excitation tests with superposed d-c excitation which recently were made on low-, medium-, and high-silicon sheet steel, and presents in detail the results for the first and the third of these three grades.

*General Electric Co., Schenectady, N. Y.

*Presented at the North Eastern District Meeting of the A.I.E.E., Schenectady, N. Y., May 10-12, 1933.*

### METHODS OF TEST

The tests were made on 20-lb laminated ring samples 9.45 in. outside diameter by 6.3 in. inside diameter. The rings were wound with uniformly distributed primary and secondary windings of 200 turns each, the primary being outside of the secondary.

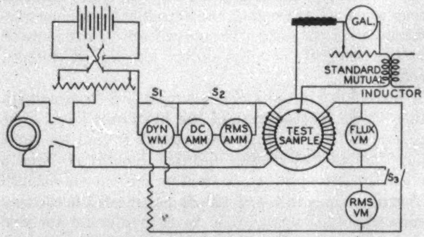

FIG. 3—CIRCUIT DIAGRAM FOR CORE LOSS AND EXCITATION TESTS WITH SUPERPOSED D-C EXCITATION

Core loss—$S_1$ open: $S_2$, $S_3$ closed
Excitation—$S_1$ closed: $S_2$, $S_3$ open

Fig. 3 shows the apparatus and circuits used, and makes clear the method of supplying the combined alternating and direct current to the primary winding of the sample. The core loss was measured with an astatic reflecting dynamometer wattmeter. The secondary voltage was measured with both a flux voltmeter[8,9] (reading average rectified voltage times 1.111) and an rms voltmeter, thus allowing both the alternating flux density and the secondary copper loss to be determined correctly for a distorted voltage wave form. The use of the two voltmeters also allowed the eddy current loss to be corrected for a distorted voltage wave form, in separating the two components of the total core loss.

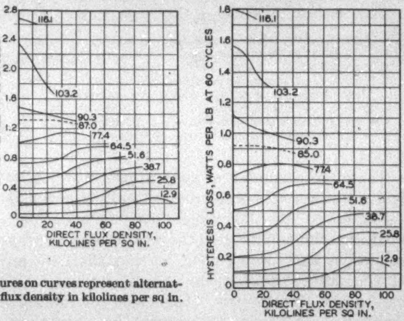
The direct flux density was measured with an overdamped ballistic galvanometer connected to a single-turn coil on the sample, deflections being read as the direct current was reversed. Several reversals were made each time before recording the deflection. A high-reactance choke coil was connected in series with the galvanometer to insure a negligible alternating current and negligible loss in that circuit. The galvanometer was calibrated by means of a standard mutual inductor, its sensitivity being adjusted by a shunt resistance.

In making the tests, the flux voltmeter reading, and consequently the alternating flux density, was held constant at each desired value while the direct current was varied in steps over as great a range as the current carrying capacity of the primary winding permitted. The sample was demagnetized each time before proceeding to the next value of alternating flux density. Considerable time was allowed between readings with no power on, in order to minimize heating of the sample, and consequent error in the calculation of the eddy current loss.

In separating the total core loss into hysteresis and eddy current components, the percentage of eddy current loss with no d-c excitation was taken from the results of numerous separation tests previously made on the same material, and it was assumed that the eddy current loss was not affected by superposed d-c excitation except as the voltage wave form was changed. At high densities, where a difference in the readings of the two voltmeters indicated a distortion of the voltage wave form, the calculated eddy current component was multiplied by the square of the ratio of the rms voltage to the flux voltmeter voltage before subtracting it from the total core loss. This correction was necessary because the calculated eddy current loss was for a sine wave form of voltage, and therefore somewhat less than that actually existing with the distorted voltage wave.

The excitation tests were made in a similar manner, except that the total rms current and the direct current were measured, instead of the power in watts. An rms ammeter and a d-c ammeter were connected in series with the primary winding, and the wattmeter and the rms voltmeter were switched out of the circuit. The a-c component of exciting current was determined from the equation

$$I_{a-c} = \sqrt{I_{total}^2 - I_{d-c}^2}$$



Figures on curves represent alternating flux density in kilolines per sq in.

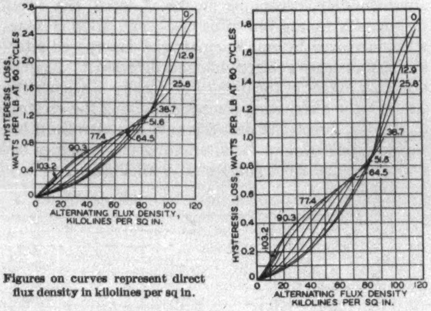
FIGS. 4 AND 5.—HYSTERESIS LOSS *vs.* DIRECT FLUX DENSITY WITH VARIOUS ALTERNATING FLUX DENSITIES, FOR LOW-SILICON STEEL (LEFT) AND (RIGHT) FOR HIGH-SILICON STEEL

### RESULTS

The silicon contents were approximately 2½, 3¼, and 4 per cent for the low-, medium-, and high-silicon steels, respectively. Each material was annealed before the samples were punched out. The low-silicon steel sample was punched from sheets 0.019 in. thick; the medium- and high-silicon steel samples were punched from sheets 0.014 in. thick.

Results are presented graphically in Figs. 4 to 11 inclusive. Only the hysteresis component of core loss is given. Alternating flux density values refer to half the amplitude of flux pulsation, and direct flux density values to the average flux density over a complete cycle; a-c excitation values refer to the effective value of the alternating component and d-c excitation values to the average current over a complete cycle.

The alternating flux density ranged from zero to 18,000 gausses (116.1 kilolines per sq in.), and the direct flux density from zero to 15,600 gausses (100 kilolines per sq in.) the highest value of the sum of the two components being approximately 20,000 gausses (129 kilolines per sq in.).



Figures on curves represent direct flux density in kilolines per sq in.

Figs. 6 and 7—Hysteresis Loss *vs.* Alternating Flux Density with Various Direct Flux Densities, for Low-Silicon Steel (Left) and (Right) for High-Silicon Steel

Throughout the range of flux density for which the solid-line a-c excitation curves of Figs. 8 and 9 are plotted, the form factor of the induced voltage did not vary from 1.111 by more than 1 per cent. For the dotted-line curves of Figs. 8 and 9, with the exception of the two uppermost curves, the form factor of the induced voltage wave did not vary from 1.111 by more than 4 per cent, and for the two uppermost dotted-line curves it did not vary from 1.111 by more than 9 per cent.

Curves for the medium-silicon steel (not included in the paper) were similar in form to those for the other two grades.

## Discussion of Results

*Hysteresis Loss.* Inspection of the curves of Figs. 4 and 5 shows that for alternating flux densities of 14,000 gausses (90.3 kilolines per sq in.) and greater, the hysteresis loss tends to decrease immediately as direct flux density is superposed; for alternating flux densities of 12,000 gausses (77.4 kilolines per sq in.) and less, it tends first to increase to a maximum, and then to decrease. For these lower densities, the hysteresis loss did not fall below the value without superposed direct flux density. However, the final slopes of some of the curves (Figs. 4 and 5) indicate that such a reduction might occur if the direct flux density were carried high enough.

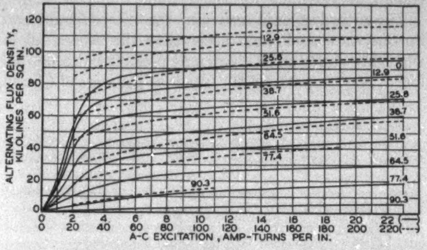


Fig. 8—Alternating Flux Density *vs.* A-C Excitation with Various Direct Flux Densities, for Low-Silicon Steel

Figures on curves represent direct flux density in kilolines per sq in.

In the range between the two densities given in the preceding paragraph, there is an alternating flux density for which the initial tendency of the hysteresis loss is neither to increase nor to decrease. It may be called the "critical" value. For the low-, medium- and high-silicon steels the critical values are approximately 13,500, 13,800 and 13,200 gausses (87, 89, 85 kilolines per sq in.) respectively. Two of these are illustrated by the dotted-line curves in Figs. 4 and 5. Values for the dotted-line curves were read from the curves of Figs. 6 and 7, the critical alternating flux density being approximately the density at which the curve for no direct flux density intersects that for 2,000 gausses (12.9 kilolines per sq in.).

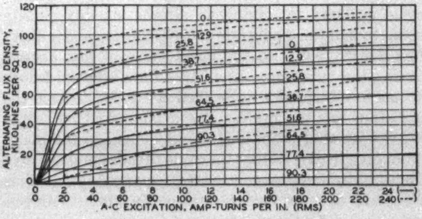

Fig. 9—Alternating Flux Density *vs.* A-C Excitation with Various Direct Flux Densities, for High-Silicon Steel

Figures on curves represent direct flux density in kilolines per sq in.

Table 4 of Doctor Holm's paper[2] shows a critical value of 13,450 gausses (86.7 kilolines per sq in.) for motor sheet steel. Table I of the paper by Chubb and Spooner[4] indicates a critical value of approximately 10,300 gausses (66.5 kilolines per sq in.) for silicon steel. Apparently none of the other investigators referred to carried the alternating component of flux density high enough to determine the critical value.

The critical value indicated by the tests of Chubb and Spooner is considerably lower than the others, all of which are nearly alike. This may possibly be accounted for, at least in part, by the fact that the tests of Chubb and Spooner were made on a transformer rather than on a ring sample as were the present tests and those of Dr. Holm.

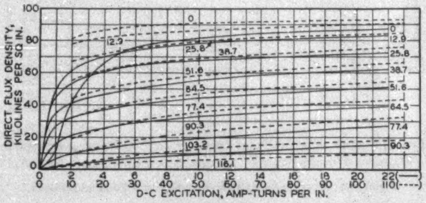

**Fig. 10—Direct Flux Density *vs.* D-C Excitation with Various Alternating Flux Densities, for Low-Silicon Steel**

**Figures on curves represent alternating flux density in kilolines per sq in.**

These results also may be used to calculate approximately the hysteresis loss which occurs when alternating flux waves of two different frequencies are combined to form a flux wave with pulsations. The loss for each cycle of the pulsation during one low frequency cycle is found by taking an alternating flux density equal to half the amplitude of the pulsation and a direct flux density equal to the mean value of flux density during the pulsation. The losses for all the pulsations in one low frequency cycle then are added to give the pulsation loss per cycle. The symmetrical hysteresis loss for an alternating flux density equal to the maximum flux density during the cycle then is added to give the total hysteresis loss per low frequency cycle. This procedure assumes that the area of the minor hysteresis loops traced by the pulsations of flux is approximately the same as that of the minor loops of the same flux density range which have been repeated many times with a constant displacement, and that the area is the same whether the upper tips of the minor loops be on the normal induction curve or on the boundary of a large symmetrical loop. The paper by Spooner[5] shows that these are approximately true, although the first minor loop is somewhat larger than succeeding ones, and the area varies slightly with horizontal displacement of the loop even though the vertical displacement is constant. The minor loops also may slightly affect the area of the symmetrical loop. Unfortunately, no data appear to be available to determine the extent of this effect.

*Excitation.* The first group of excitation curves (Figs. 8 and 9) shows that for any given alternating flux density, superposed d-c excitation increases the required a-c excitation. The solid-line curves of Figs. 8 and 9 represent the rms excitation corresponding to a sine wave of induced voltage, since for the range they cover, the form factor of the induced voltage was within 1 per cent of 1.111. The values of excitation given in the dotted-line curves, for which the wave form became somewhat distorted, are higher than would have been obtained with a sinusoidal voltage wave.

The second group of excitation curves (Figs. 10 and 11) shows the effect of superposed a-c excitation on the direct flux density and the d-c excitation. In the range from zero up to 11,200 gausses (72 kilolines per sq in.) approximately, depending on the material, the direct flux density for a given value of d-c excitation is somewhat increased by small amounts of superposed alternating flux density; larger amounts decrease it. Neither the exact extent of the direct flux density range nor the value of the alternating component giving the greatest increase of direct flux density could be determined because of lack of data for alternating flux densities between zero and 2,000 gausses (12.9 kilolines per sq in.) Direct flux densities above this range are not increased at all by superposed a-c excitation, but are immediately decreased.

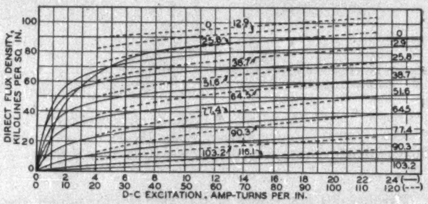

**Fig. 11—Direct Flux Density *vs.* D-C Excitation with Various Alternating Flux Densities, for High-Silicon Steel**

**Figures on curves represent alternating flux density in kilolines per sq in.**

## CONCLUSIONS

1. These tests constitute an addition to existing core loss and excitation data which will be helpful in designing apparatus in which combined alternating and direct magnetic fields occur. They will assist also in predicting the performance of existing designs when subjected to similar conditions of magnetization.

2. Both alternating and direct components of flux density were carried to high values. Corrections were

made for distortion of the voltage wave form at high densities.

3. In the range of alternating flux density below a certain value, which may be called the "critical" value, hysteresis loss tends first to rise, then to reach a maximum, and finally to decrease, as d-c excitation is superposed and the alternating component of flux density is held unchanged. Superposed d-c excitation decreases the hysteresis loss for any given alternating component of flux density in the range above the critical value.

4. The critical value of alternating flux density for silicon steel lies in the range 13,200 to 13,800 gausses (85 to 89 kilolines per sq in.).

5. The a-c excitation for any given alternating flux density is increased by superposed d-c excitation.

6. The d-c excitation for a given direct flux density in the low or moderate density range is decreased by a small amount of superposed a-c excitation, but is increased by larger amounts. The d-c excitation for a given direct flux density in the high-density range is increased by superposed a-c excitation.

## Discussion

**S. L. Gokhale:** Most of the work on this subject has been conducted by engineers and along lines representing the engineer's point of view. All such work, including Mr. Edgar's contribution, has added greatly to our knowledge of facts regarding magnetic hysteresis. It must be recognized, however, that from the physicists point of view, we are yet very much in the dark. Fig. 1c in Mr. Edgar's paper, shows the forms of two hysteresis loops for the same range of flux change, one symmetrical and the other unsymmetrical. The latter is unsymmetrical not only in position but also in form; the ascending and descending sides of the loop are dissimilar. Why are they so? The unsymmetrical loops generally are larger than the symmetrical. Why? In some cases, this relation is reversed, the unsymmetrical loop being the smaller. Why? These and other cognate questions are still unanswered. The duty of seeking answers to these questions rests not on the engineers but on the physicists.

These questions suggest another much more fundamental question. Why is it, that we know so little about magnetism, although we know comparatively so much more about electricity, and although the two branches of physical science not only are related but also analogous? It seems as if some special obstacle to knowledge has developed on the magnetic side, without affecting the electrical side. Is there really such an obstacle, and if so what is it?

In 1852, Weber formulated his well-known theory of magnetic phenomena. He assumed, that a magnetic body is made up of molecular permanent magnets, and that the process of magnetization consists of orientation of these molecular magnets, under the directive influence of a magnetizing force, $H$. According to this theory, the magnetic flux density $B$ at any point, is a magnetic force of the same nature as $H$, with this difference, that $B$ is the resultant force of which $H$ merely is one component; the other component is the magnetic force emanating from the poles of the molecular magnets. This conception of $B$, leads to the conclusion that permeability is a non-dimensional quantity. This relationship between Weber's molecular-magnet conception, and the non-dimensional conception of permeability, however, is not generally recognized; consequently, there are many scientists to-day who advocate the Weber's theory of magnetism either in its original form, or in its modern modified form based either on molecular currents, or on electronic orbits, and they also advocate the dimensional conception of permeability.

In 1886, Ewing formulated his theory of permeability and magnetization based on Weber's conception. He thus explained successfully, the general forms of magnetization and hysteresis curves, and also other associated phenomena such as magnetic creeping. He also explained some of the peculiarities of hysteresis loops such as the failure of the loops to close, and of successive loops to retrace the preceding loops during the initial cycles.

Ewing's work was mostly qualitative: quantitatively, he had succeeded in making, what we might call the first approximation; that is, in computing the magnetic forces on the molecular magnets, he had taken into account only the nearest poles, and had left out of consideration the relatively distant poles of even the same molecules (Ewing: "Magnetic Induction in Iron," p. 172). In 1892, Steinmetz carried Ewing's theory of hysteresis one step further; Ewing had taken into account only one pair of poles, namely, the two nearest poles of a pair of molecules; Steinmetz took into account all the four pairs of the poles of these molecules (A.I.E.E. Trans., 1892, p. 718). His next effort was to be a more elaborate computation of forces on a molecular magnet due to a large number of molecular magnets in its neighborhood. It seems that this work was not completed, and in the meantime an unforseen difficulty had arisen.

In 1889, Rucker formulated his theory of "suppressed dimensions;" according to that theory permeability is a dimensional quantity; the dimensions are not yet known, but are believed to be related to the dimensions of velocity. This theory rapidly gained in popularity and is now accepted by a majority of scientists. As stated above, Rucker's theory and Weber's theory are opposed to each other, and that the acceptance of the one necessarily involves a rejection of the other theory. The contradictory nature of the two theories generally is not recognized, because those who accept both are generally content with a formal acceptance, without any attempt to carry each theory to its logical consequence.

In accepting the dimensional conception of permeability, we have perhaps unconsciously rejected a very valuable analytical instrument for magnetic research. In other words, our lack of correct and clear understanding of magnetic hysteresis, is the price we are now paying for the dimensional conception of permeability. This is not an argument against Rucker's theory. If the theory be true, we have got to accept it no matter what price we have to pay for it; but before we pay that or any other price, we must have some evidence in support of that theory.

Therefore, while our engineers are collecting data on magnetization and hysteresis, evolving ingenious methods for the work, it is for the physicists to tackle the fundamental problems in order to account for the phenomena in a rational way. The problem that seems to be at the root of most of the other problems in magnetics is, whether permeability is a dimensional or a non-dimensional quantity. Until that question is answered with convincing evidence in support of the answer, there seems to be no likelihood of a rational explanation of the magnetic phenomena.

**C. MacMillan:** The data given in the paper should prove valuable to designers of various types of electrical apparatus. The cases to which the results immediately are applicable are confined to those in which the superposed fields are in line with a common axis. However, the data should also afford assistance in cases involving more complex conditions, and field axes which are not necessarily in alignment. Such conditions occur, for example, in the magnetic circuits of induction motors. In the vicinity of the air gap, the general direction of the useful flux is radial, that of the leakage flux peripheral, yet in their use of common permeance paths, these fluxes approximate more closely to the conditions covered by the paper.

As shown in the paper, the fundamental a-c current may be taken to represent the d-c displacement mmf upon which is superposed the high frequency pulsation of mmf induced by the non-uniform and non-sinusoidal distribution of teeth and windings. The magnitudes involved bring this case into the class in which reduction of iron loss with high density might be anticipated since the flux displacement does, in practice, frequently exceed the critical values given in the paper. Thus, we may expect locally the conditions for reduced losses which rarely are encountered on a more extended scale on account of the large mmf's and currents required to establish them.

In applying the data on superposed losses, or losses due to superposed mmf's to the calculation of induction motor core loss, we have found that the computed loss may be brought into closer agreement with test results. However, in some cases, the calculated values exceed the test values. The discrepancy may be due in part, at least, to reductions of the type described in the paper, and to which due weight had not been given in the methods used for calculation. Where the discrepancies are in the opposite direction, it is more difficult to assign causes since they may be due to defective care in manufacture.

Attention has been called, in previous discussion, to the unsatisfactory state of our knowledge of magnetic processes. Even the discussor who contrasted favorably present knowledge of metals with present knowledge and lack of knowledge of non-metals, such as dielectrics, would probably make an exception in the case of the magnetic properties of metals. If the increased training in analysis advocated by Professor Karapetoff is successful in developing graduates of greater analytic ability, possibly this stigma may be removed from the record of engineers, namely, that with the consistent records of magnetic behavior before our eyes so constantly for so many years, we have hitherto failed entirely to interpret these records.

**B. M. Smith:** The method of measurement and equipment shown in this paper has certain refinements not used by previous investigators. It should, therefore, give results which are more reliable than hitherto obtained. The data presented by the author show agreement in several instances with those obtained by the investigators referred to, and also furnish new data beyond the range previously reported.

The fact that hysteresis loss decreases with superposed direct current has in the past given engineers encouragement to believe that it would be possible to obtain lower core loss in power transformers by this means. The data given in this paper, however, show that, although the hysteresis loss is decreased, there is a proportionately greater increase in the exciting current, which would indicate that the application of direct current could not be used for decreasing transformer losses. The tests, however, do not cover superposed alternating current.

In the numerous articles written on superposition of direct current on alternating current, it has been recognized that the hysteresis loss decreases when the hysteresis loop is displaced from its symmetrical position, but in none of these articles has an explanation of this phenomenon been given. It has, however, been mentioned that it is due to a change in shape and area of the hysteresis loop, but the writer believes it would be interesting if the author would give his explanation as to how this is affected.

**R. F. Edgar:** As pointed out by Mr. Gokhale, a fundamental explanation of the variation of hysteresis loss with displacement of the hysteresis loop apparently is unknown as yet, and further discussion of the various theories involved is beyond the scope of the paper. However, there is an association of the change of shape of the loop with its change of area, as suggested by Mr. Smith, which is given below.

Inspection of the series of loops published by several of the authors previously mentioned shows that as a loop is displaced upwards from a symmetrical position, keeping a constant amplitude of flux pulsation, the lower end tends to expand, while the upper end tends to contract. For combinations of flux pulsation and displacement which carry the upper end of the loop to very high densities, the contraction of the upper end apparently overbalances the expansion of the lower end, and the area of the loop is reduced.

# Variable Speed Constant Voltage D-C Generators

BY FRED B. HORNBY*

Associate, A.I.E.E.

***Synopsis.***—*Generators for producing essentially constant voltage when operating from a variable speed source have been developed. Two types of variable speed constant potential generators are described that obtain regulation without the use of regulators having moving parts. One type makes use of a thyrite regulator to obtain the desired characteristics. The other type is inherently self-regulating and, therefore, requires no external regulation. These generators are sufficiently flexible to allow a wide variation in their design and operating characteristics.*

* * * * *

APPLICATIONS for variable speed constant voltage d-c generators and generating systems have been many and varied. Generators with vibrating or carbon pile voltage regulators which have been used for variable speed constant voltage applications have been found inadequate because they will not operate satisfactorily when subjected to repeated vibration. The injurious effects of vibration have lead to the desire to have a generating system that can be regulated either by inherent generator characteristics or by a regulator that has no moving parts. The thyrite controlled generator system and the self-regulating generator have been developed to meet these requirements.

## THYRITE CONTROLLED GENERATOR

Before taking up a thyrite controlled generating system, it will be well to deal briefly with the characteristics of the material known as thyrite. Thyrite is a ceramic material having a mechanical strength about the same as high-grade porcelain. The most satisfactory shape for generator control is a disk 3 in. in diameter and 1/8 in. thick. The electrical characteristics of thyrite are a part of the ceramic bond and are not dependent on any fillers or mechanical contacts. The fundamental law of thyrite is stated by the equation $RI^2 = C$, in which $R$ is the resistance of the thyrite, $I$ is the current, $C$ is a constant coefficient, and $a$ is a constant equation. The exponent $a$ depends entirely upon the quality of the material and is less than unity, typically 0.72. The coefficient $C$ depends on the specific physical dimensions of the thyrite unit. The operation of thyrite is not dependent upon the temperature, but the material does have a negative temperature coefficient. This negative coefficient has about the same numerical value as the positive coefficient of copper. An increase in voltage across a thyrite unit will result in an increase in current by approximately the 3.57 power of the voltage increase. It is this negative resistance characteristic that makes it so useful as a regulator.

The connection of the thyrite unit as a control for a generator is shown schematically in Fig. 1, wherein the unit is in series with an auxiliary field which is wound on the same pole as the shunt field. The auxiliary field is so connected that the magnetomotive force produced by the auxiliary field is in opposition to that produced by the shunt field. If the generator terminal voltage increases, the thyrite allows proportionately more current to pass through the auxiliary field than passes through the shunt field, with the result that the difference in magnetomotive force of the two fields decreases, thereby decreasing the flux in the machine and limiting the increase in generator voltage. The performance of a typical thyrite controlled generator is shown in Fig. 2. As may be seen, the flux in the machine decreases as the speed of the generator increases, the flux approaching zero as a limit.

The thyrite acts not only as a regulator, but also as a stabilizer and makes it possible to operate the generator at fields much weaker than normally would be practical. Generators controlled in this manner have shown perfect stability, although the flux in the generator was less than 10 per cent of the normal flux. This type of control also will produce very good generator load regulation as shown in Fig. 3. Both the operating stability and the flat compounding are obtained by the regulator attempting to hold constant generator voltage. The effect of heating on the thyrite system is much the same as the effect of heating on a standard d-c generator. An increase in temperature will produce the usual drooping voltage characteristic.

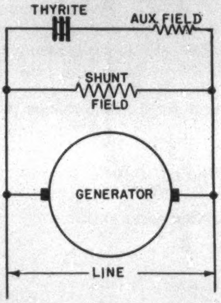

FIG. 1—SCHEMATIC DIAGRAM OF A THYRITE CONTROLLED GENERATOR

The design of thyrite controlled generators should be such that the peak of the flux curve is reached at approximately the rated base speed of the generator. Consider the design of a machine having ideal conditions wherein a straight line saturation curve is obtained. Saturation will further increase the necessary size of the machine. Since the heating of the fields is the limiting feature in the design of a thyrite controlled generator, a consideration of the fields necessary to produce the required characteristics will give an idea of the size of machine necessary.

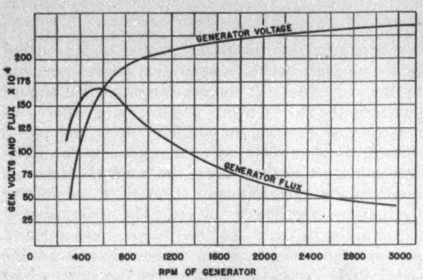

FIG. 2—SPEED REGULATION AND FLUX CURVES FOR A THYRITE CONTROLLED GENERATOR

### GENERAL CONSIDERATION OF FIELDS

Assume circuit connections as shown in Fig. 1.

Let

$A$ = shunt field ampere-turns
$B$ = auxiliary field ampere-turns
$AT$ = effective ampere-turns = $A - B$
$K_e$ = ratio of thyrite current for a given change in terminal voltage
$K_\theta$ = ratio of flux change, $\theta_2 = K_\theta \theta_1$
$K_v$ = ratio of voltage change, $V_2 = K_v V_1$
$K_s$ = ratio of speed change, $S_2 = K_s S_1$

Assume straight line saturation curve so that

$$V \alpha A - B$$

Since

$$\theta = \frac{CV}{S}$$

then

$$K_\theta = \frac{K_v}{K_s}$$

With this scheme of connection

$$A_2 = K_v A_1 \text{ and } B_2 = K_e B_1$$

$$A_2 - B_2 = K_\theta (A_1 - B_1)$$

$$B_1 = A_1 \frac{K_v - K_\theta}{K_e - K_\theta} = A_1 X$$

where

$$X = \frac{K_v - K_\theta}{K_e - K_\theta}$$

$$A_1 = \frac{AT}{1 - X}$$

Expression for total field ampere-turns at base speed

$$A + B = A_1 (1 + X) = \frac{AT (1 + X)}{1 - X}$$

*Example.* Consider a machine having 2 to 1 speed ratio and 1.5 to 1 voltage ratio.

$$K_s = 2 \qquad AT = 1{,}000$$

$$K_v = 1.5 \qquad K_\theta = \frac{1.5}{2} = 0.75$$

$$K_e = 4.5$$

$$X = \frac{1.5 - 0.75}{4.5 - 0.75} = 0.20$$

$$A_1 = \frac{1{,}000}{1 - 0.20} = 1{,}250 \qquad B_1 = 250 \text{ amp-turns}$$

$$A_1 - B_1 = 1{,}000$$

$$\text{Total ampere-turns in field at } S_1 = \frac{1{,}000 \times 1.2}{0.8}$$

$$= 1{,}500 \text{ amp-turns}$$

Ratio of total to effective ampere turns of $S_1 = 1.5$.

Examination of general equations and specific examples brings out two main facts:

1. The closer the regulation over a given speed range, the larger the field.

2. The greater the speed range, the larger the field for a given regulation.

The necessity of having the actual field winding over 1½ times the normal field requires a theoretical increase in the size of the machine. Saturation of the iron makes it necessary to have a still larger machine since with saturation the change in field strength is not reflected in change in flux. The necessary increase in field space together with the necessity of having low iron density results in a practical increase in machine size very close to the increase in field size given by the foregoing approximate calculations. Results have shown that the figure arrived at by such a calculation

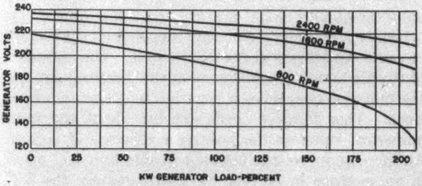

FIG. 3—LOAD REGULATION CURVES FOR A THYRITE CONTROLLED GENERATOR

can be used as an index to determine the necessary dimensions of a specific generator.

Obviously, the increase in frame size becomes an economical limitation as the output of the generator increases. This increase in cost and size may be readily overcome by applying an exciter to the generator and the thyrite control to the exciter field instead of the generator field. The exciter will be oversize, but since it is a small machine, this increase is a reasonable factor when it is considered along with the main generator. When applying an exciter, it is advisable to excite both of the exciter fields from the main generator terminals. This makes the action of the exciter directly dependent on the generator voltage.

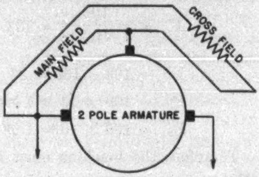

FIG. 4—SCHEMATIC DIAGRAM OF A SELF-REGULATING GENERATOR

The generator-exciter combination makes a thyrite system that is simple, economical, and capable of satisfactory operation in a wide variety of applications. There are, of course, limitations to this system and type of control, but these limitations have not been broadly determined; and since they are readily found when specific machines are considered, no attempt will be made to describe them.

### SELF-REGULATING GENERATOR

In his paper, *A D-C Generator for Constant Potential at Variable Speed* (A.I.E.E. TRANS., 1918, V. 37, Part II, pp. 1405-12) S. R. Bergman described a very practical machine for producing constant voltage, the regulation being entirely inherent. A machine giving regulation without a regulator of any kind has several advantages. The fundamental theory of this machine is described fully in Mr. Bergman's paper. Demands for this type of equipment have increased greatly, and speed ranges and duty cycles have become more severe. For this reason, it seems desirable to discuss further this machine and its design.

A schematic diagram of connections is shown in Fig. 4. Other connections are possible, however, and it would be well to consider some of these as they have a definite bearing on the design of the machine. The main field may be excited from a separate source, but it may not be excited from the main line of the generator without special connections and an auxiliary field as shown in Fig. 5. If the main field be excited from the main brushes of the generator without these precautions, the generator will experience difficulty in "building up," because the residuals of the main and cross fields are bucking each other. Also, the machine will have a tendency to reverse polarity if rapid changes in speed occur. Under all conditions, the cross field must be excited from the voltage produced by the main field flux. With connections as shown in Fig. 5, the main field may be connected across the main line and satisfactory operation obtained. The auxiliary field is connected in the same direction and is wound on the same pole as the main field; it acts merely as a "teaser" winding which starts the generator to build up and prevents a reversal of the generator polarity during the transient period.

When the generator is connected as shown in Fig. 4, the main field heating increases as the square of the increase in excitation voltage; thus it is necessary to design the field so that it will produce normal ampere-turns at the base speed and at the same time dissipate many times more than normal heating at top speed. The cross field produces normal ampere-turns at top speed and is, therefore, a normally balanced field. With the generator connected as shown in Fig. 5, the auxiliary field must be designed for normal excitation and many times normal heating; but the auxiliary field is in itself a very small field so that this problem is not serious.

From the preceding discussion it may be seen that connections shown in Fig. 4 can be used for generators having a small speed range, but for generators having a large speed range, the connections shown in Fig. 5 are better. If a separate source of power is available for exciting the main field, connections in accordance with Fig. 4 (except the main field excited from this separate source) are satisfactory for generators of any speed range.

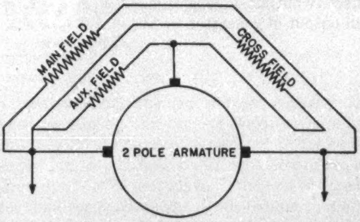

FIG. 5—SCHEMATIC DIAGRAM OF A SELF-REGULATING GENERATOR WITH AUXILIARY FIELD

Since the generator operates on the difference of two voltages, the size of this machine will be larger than that of a standard generator of the same rating. In these machines, heating of the fields is a limiting factor, but not the only one, for armature heating also affects the rating. The following consideration of the various factors gives a definite figure for the increase in size necessary for a given rating.

## DETERMINATION OF VOLTAGES INDUCED FROM MAIN AND CROSS FIELDS

Let

$X$ = volts induced from main field
$Y$ = volts induced from cross field
$Z$ = terminal volts
$S$ = speed ratio
$R$ = voltage ratio
$K$ = main field flux increase factor
$C$ = cross field flux factor
$I_r$ = rated generator current at base speed, including field current

$$X_1 - Y_1 = Z_1$$

$$X_2 - Y_2 = RZ_1$$

$$X_2 = KSX_1$$

$$Y_2 = CS^2Y_1$$

$$R(X_1 - Y_1) = X_2 - Y_2$$

$$X_1 - Y_1 = \frac{KSX_1 - CS^2Y_1}{R}$$

$$X_1(KS - R) = Y_1(CS^2 - R)$$

$$Y_1 = X_1 \frac{(KS - R)}{(CS^2 - R)} = X_1 m$$

where

$$m = \frac{KS - R}{CS^2 - R}$$

$$Z_1 = X_1(1 - m)$$

$$X_1 = \frac{Z_1}{1 - m}$$

Effective output of generator = $(X_1 - Y_1)\, I_r = P_e$; actual output of generator = $(X_1 + Y_1)\, I_r = P_a$.

## EXAMPLE

Consider a machine having a 2 to 1 speed ratio and 1.5 to 1 voltage ratio with connections as shown in Fig. 4.

$Z$ = 100 volts $\qquad K = 1.12$
$S = 3 \qquad C = 1$
$R = 1.5 \qquad I_r = 10$

$$m = \frac{(1.12 \times 3) - 1.5}{9 - 1.5} = 0.248$$

$$X = \frac{100}{1 - 0.248} = 133$$

$$Y = 133 - 100 = 33$$

$$P_e = 100 \times 10 = 1 \text{ kw}$$

$$P_a = 166 \times 10 = 1.66 \text{ kw}$$

Therefore the machine must be 1.66 times normal size.

Generators making use of the bucking field principle have been built for many years and their operation has been quite satisfactory. There are, of course, limitations to this type of equipment, but except the increased size, weight, and cost, the limitations are peculiar to the application and cannot be considered as general difficulties to be overcome. Detailed comparison of these two types of machines with each other and with other types of variable speed constant voltage equipment is outside of the scope of this paper. Such comparison when made should be on the basis of the total equipment including all regulating devices and controls, and not on the basis of the generator alone.

# Design of Resistance Welder Transformers

BY H. E. STODDARD*

Associate, A.I.E.E.

***Synopsis.****—Due to increased production demands, the speed at which resitance welders operate has been stepped up as much as four to five times during the last few years. This has been made possible in a large degree, by the development of new switching mechanisms that will allow a current dwell of a fraction of a cycle on a 60-cycle circuit.*

*This increased speed of welding has made it necessary to study very carefully the design of the transformer and the shape and spacing of the secondary circuits, especially the cooling and protection of these parts.*

*It has been necessary also to pay more attention to multi-transformer welders, where several transformers are used either for the purpose of distributing the secondary current to better advantage, or for the purpose of balancing the welder load on multi-phase circuits.*

IN the last few years manufacturers have been called upon to produce welders that will weld at very high speeds. Spot welder speeds have increased from a maximum of about 150 to 200 spots per minute of ten years ago to a maximum of 900 spots per minute today, with the indication that this speed can be increased to perhaps as much as 1,800 spots per minute. Also in the last few years control units employing grid-controlled gas or mercury-vapor filled electronic tubes have been developed and applied to spot and seam welders for high speed welding. The time of current dwell can easily be reduced to one cycle on a 60-cycle circuit. Also several switching mechanisms driven by synchronous motors have been developed and put in use and it is claimed that they will operate at such speed that the current dwell can be reduced to ½ cycle or less on a 60-cycle circuit.

Welders other than spot welders have been increased in speed, but not in the same proportion. Ordinary flash butt welding is being done at an average speed of about 7 sec for the complete welding cycle on work up to about 10 sq in. Smaller sections are welded in less time, and larger sections in longer time. Therefore the welders, including the transformers, are continually increasing in size and capacity for the same size of weld, and the problems of the design are being increased in proportion.

Very little technical work is involved in the ordinary design, but considerable experience is necessary in selecting the proper secondary voltage, estimating the correct power required, proportioning the transformer core and coils properly so that mechanical design of the welder is not upset, designing the secondary circuit from the transformer to the work, providing the proper shielding for the transformer, etc.

A resistance welding transformer has a peculiar duty to perform. It must be of great enough capacity to deliver the number of amperes at the weld required for welding the largest section for which the machine is used. It must also be of great enough capacity to permit of welding the greatest number of square inches per hour for which the machine is purchased. It must do all this without heating to a point to injure the insulation. Furthermore, it is not the internal resistance of the transformer only which tends to heat it, for there is the heat conducted back into the transformer secondary by conduction, and to other parts of the transformer by radiation and convection.

The problem is not to design a transformer of specified capacity, but to design a transformer and secondary circuit that will cause enough electric current to flow through the work and heat it properly so that with the correct application of pressure a weld is completed.

The transformer capacities are estimated mainly by considering the size of material to be welded, the speed at which it must be welded, the type of weld to be used, and mechanical design of welder. The types of welds are as follows:

1. Spot welds
    Projection welds (single projection, multi-projection)
    Point welds (single spots, spot seams)
2. Butt welds
    Upset welds
    Flash welds (manually controlled, mechanical controlled)
    Contact flash or high speed upset welds
    Butt seam
3. Line or seam welders
    Continuous
    Interrupted

In butt welding, the transformer capacity is influenced greatly by the type of weld, as flash welds require only 20 per cent to 25 per cent of the capacity necessary for contact flash welds, and slow upset welds require only about 25 per cent to 50 per cent of the capacity required for flash welds. If we assume that a flash weld will be made in 7 sec, then a slow upset weld will take about 15 to 30 sec, and a contact flash weld about 1 to 2 sec, provided the pieces to be welded are adaptable to either type of weld.

Multi-projection welding requires sometimes as much as two to three times the capacity for one weld times the number of welds. This increased capacity is principally due to the fact that nearly always one weld is partly made, first, causing an increase of current at that point. Therefore there must be enough capacity to take care of this. This increased capacity is also influenced by the shape of the work, size of weld, and the shape and size of electrodes when they may restrict the proper distribution of the welding current.

## TRANSFORMER CORE

The core is usually built up of 29 gauge silicon steel in one or two window shapes. Sometimes the single window cores are split and after assembly they are machined so that they fit together with little air gap. This split core is used when it is necessary or convenient to have an easy way of disassembling the transformer for changes or repairs.

## TRANSFORMER SECONDARY

The secondary may be either flexible for its entire length, or it may be solid and have a short flexible lead connected to the moving terminal of the welder. The flexible secondary is made up of thin copper strips, usually 0.005 in. to 0.008 in. thick and they may be made up of narrow strips and sandwiched between pancake primary coils (see Fig. 2), or of wider sheets and wound around the outside of the primary coils (see Fig. 1). There is some objection to both of these types of secondary. One objection to the narrow type is that the primary coils cannot be wedged properly, and the objection to the wide type is that the design of the transformer is not as adaptable to changes as the narrow type would be.

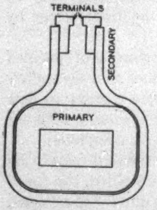

FIG. 1 (LEFT)—WIDE FLEXIBLE SECONDARY OUTSIDE OF PRIMARY COILS

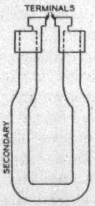

FIG. 2 (MIDDLE)—NARROW FLEXIBLE SECONDARY SANDWICHED BETWEEN PRIMARY COILS

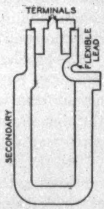

FIG. 3 (RIGHT)—CAST SECONDARY CONNECTED TO MOVING TERMINAL BY SHORT FLEXIBLE LEAD. SECONDARY SANDWICHED BETWEEN PRIMARY COILS

Solid secondaries are made of cast copper, cast aluminum, rolled copper, and sometimes of the work itself. Where castings are used for secondaries, they are usually water cooled by either casting steel tubing in cast copper, copper tubing in the cast aluminum, or by holes drilled for a water circuit. Cast copper is used principally and has less disadvantages than any other cast material. The disadvantages to cast aluminum are that it must be double the area of cast copper, and high resistance oxides form rapidly on the machined contact surface under the influence of heat and water. Rolled copper is used very little for solid secondaries, due principally to the difficulty of connecting the ends to the terminals of the welder, as each section of the secondary must be silver soldered or welded to a suitable header; since there is a large mass of metal, it is a difficult and expensive job. Rolled copper does make a good secondary, and on some welders where forced air can be used for cooling the transformer, it is used. See Figs. 3, 4, and 5 for different shapes of cast secondaries for butt welders, and Figs. 6 and 7 for shapes of circuits for small spot welders.

The secondary proper is shaped so as to minimize the eddy current losses. The terminals and flexible leads are designed with proper contact surface areas where electrical connections are made. These areas are of such size as to keep the current density to about 225 amp per sq in. when connected to aluminum; to about 550 amp per sq in. when connected to cast copper; other materials generally fall within these limits. Conditions often alter these values.

## PRIMARY COILS

The secondary voltage of a resistance welder is changed either by changing the primary voltage or by using a selector switch connected to tapped primary coils to change the turn ratio. Generally the minimum secondary voltage is 40 per cent to 50 per cent of the maximum. This, of course, depends upon the kind of welding to be done. Usually about 10 to 16 different secondary voltages are provided; therefore 6 to 8 taps are necessary for the secondary voltage range. The tapped primary is generally used, although there is some objection to it. When the transformer is being operated on the maximum secondary voltage, the voltage across the outside turn of the primary coil is about two times the primary voltage. Also as about one-half of the primary is out of the circuit, the magnetic leakages may be increased considerably, but by using care in the design these objections can be minimized to a large extent.

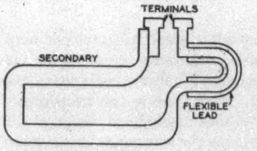

FIG. 4—CAST SECONDARY CONNECTED TO MOVING TERMINAL BY FLEXIBLE LEADS. SECONDARY SANDWICHED BETWEEN PRIMARY COILS. TRANSFORMER OFFSET FROM WELD LINE

Sometimes especially in large welders the coils are not tapped, but an autotransformer with tapped coils is used for secondary voltage variation, in this way getting around the objections mentioned; but in doing so there is added another piece of apparatus which must be installed near the welder and therefore is in itself not desirable. Generally either type of transformer is equally acceptable. However, on some of the larger types of welders, autotransformers are demanded and in addition sometimes an inductive voltage regulator is used to get micrometer voltage adjustments between taps on the autotransformer.

The primary coils and the coils of autotransformers are usually wound of bare copper strip and insulated between layers with asbestos paper tape. As little insulation as practical is used on the outside of the coil in order that the heat may be dissipated as rapidly as possible. Although the secondaries of most welder transformers are water cooled, this helps very little in cooling the primary, and the natural air draft is depended upon for this cooling.

### TRANSFORMER RATING

The Resistance Welder Manufacturers Association rating is based on 50 per cent duty cycle, which was selected because very few welders are operated at higher than 50 per cent duty cycle and because it corresponds quite closely to the majority of welders in use previous to this rating. The primary is designed for a current density of 1,800 amp per sq in.; the secondary for 1,600 amp per sq in. if made of cast copper; 800 amp per sq in. if made of cast aluminum, and the core is designed for a density of 70,000 lines per sq in. at the maximum secondary voltage.

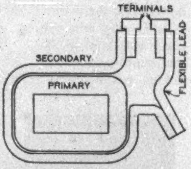

FIG. 5—WIDE CAST SECONDARY TO FIT OUTSIDE PRIMARY COILS. TRANSFORMER OFFSET FROM WELD LINE

### MECHANICAL PROBLEMS

The mechanical problems in the design consist of: First, shaping the transformer so that it fits into the welder properly; second, making the core and core clamping frames, primary coils, and secondaries of such shape and material that they can be made and assembled without too great an expense, and without sacrificing more than is necessary in the efficiency and power factor of the completed welder; and third, the shielding of the transformer from the metal thrown off by the weld and also from water and oil.

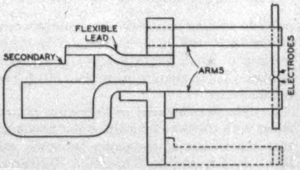

FIG. 6—TOP CONNECTED SPOT WELDER

The fact that a large percentage of designs are for special apparatus where perhaps only one transformer is to be built, makes these problems quite important. Shaping the transformer properly so as to fit the welder is relatively simple, and can usually be accomplished. A 40-kva or 50-kva transformer can be built so it will go in a space only 4 in. wide; of course it must be extended considerably in other directions. The core and clamping frames also are easily handled. The difficulty comes in the secondary, secondary leads, and the terminals. The secondaries should be made as high and as thin as possible. Where water cooled secondaries are called for, they must be thick enough so that a tube can be cast in for a water duct, and this requires that the casting be about 0.5 in. thicker than the diameter of the tubing to prevent its floating out. Also, as far as possible, the tubing must be cast in so that it is parallel to the current flow, and the tubing must be as straight as practicable so that it can be cleaned out if it fills up with rust or dirt. The finished secondary is always a compromise between good electrical practise and the desired mechanical features.

The terminals of the welder are necessarily well cooled, not only to dissipate the heat due to the flow of current, but to dissipate the heat conducted into them by the weld itself, and since the terminals are under very heavy pressure, it is necessary to keep the temperature as low as possible.

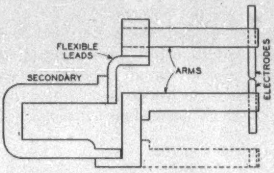

FIG. 7—BOTTOM CONNECTED SPOT WELDER

The flexible leads are also a compromise. Electrically they should be as short as possible, and mechanically they must be long enough to allow the terminal plenty of movement, and also they must be of proper shape to insure long life.

The mechanical difficulty met with concerning the primary coils, is to bring out the taps and the start and finish of the coils so that the minimum space is required, also to brace the primary effectually against the surges that are always present.

The shielding of the transformer also is very important, especially on flash butt welders. It is necessary to keep the metal thrown off by the weld from the primary coils. This metal is in the form of fine dust and if allowed to sift in between coils soon penetrates the insulation and causes short circuits or grounds. Also, there is always a large amount of water used around resistance welders, especially line or seam welders, where the work is sometimes flooded with water. Therefore, it is necessary to make the primary coils nearly waterproof.

### MULTIPLE TRANSFORMERS

In some welders it is necessary to use more than one transformer. Four general types of multi-transformer welders are:

1. Welders for making fabric for reinforcing mats used in concrete road building, where as many as 32 transformers are used and 32 welds are made simultaneously, each transformer making a weld which is separated from the next weld enough so that no particular difficulty is experienced.
2. Large spot welders are sometimes provided with two transformers, one transformer on the bottom and one on the top of the work. Each end of the secondary of both transformers is connected to an electrode, the top electrodes being directly over the lower electrodes when the work is placed between them. The secondaries are in series. No particular advantage is gained however.
3. Welders used for making very long butt welds where multi-transformers are convenient for distributing the current properly over the entire weld. These transformers are connected in parallel on a single phase circuit.
4. Large projection spot welders where the work is distributed properly. Three transformers are sometimes used and connected each to one leg of a three-phase circuit.

In the third type of welder mentioned where the transformers are operated in parallel, the principal difficulty is in the secondary circuits. Unless these circuits are all of the same resistance and impedance, the current distribution will not be correct.

In the fourth type mentioned, the same difficulties are experienced and in addition to these the fact that the work causes a partial short circuit between phases makes it difficult to design electrodes to minimize this short circuit so that the work can be done efficiently.

### POWER FACTOR

The power factor of resistance welders varies considerably with the type and construction of the apparatus. On some types of welders, it may be as high as 65 per cent or 70 per cent; on other welders, it may be as low as 20 per cent.

Resistance welder manufacturers are of course interested in methods of increasing this power factor. The first idea is to better the design of the transformer and connections, but since the design is limited so closely by mechanical requirements for protection of the transformer and for the proper movement of the welder terminal, very little increase in power factor may be secured. Therefore, it seems as if any substantial increase of power factor must be made by the use of some outside piece of apparatus.

---

## Discussion

**Warren C. Hutchins:** As indicated by the author, developments in resistance welding have been very rapid in the last few years. In fact in the writer's company one man was given the task of correlating data on resistance welding with reference to the power, time application, pressure of electrodes, recommended speed of travel for various types of spot and line welding. After this particular individual had spent approximately 3 or 4 months on this work and had collected enough information to fill several volumes, an electronic tube control named thyratron control was furnished to the Works Laboratory for experimental purposes. After about two or three weeks experimenting, it was found this control permitted welding in such greatly reduced time periods for spot welding and at such greatly increased linear speeds for line welding machines that practically all of the data previously collected were worthless.

Thyratron tubes were first applied to controlling resistance welding machines only a few years ago. The development of this control passed through the following stages:

1. To replace the mechanical contactors and eliminate the maintenance cost of the contactors. The average expected life of thyratron tubes for this service is 10,000 hours. This control was used for welders up to 350 kva capacity. For timing the on and off period a small 1-ampere switch was used. This switch usually was cam operated and the accuracy of timing was no better than the switch.

2. To the first control developed, a thyratron synchronous timer was applied which eliminated variations in the time current supplied to the welding machine. This permitted more consistent welding and increased welding speed. It also made possible welding in exactly one cycle or any multiple of one cycle of any frequency up to approximately 500 cycles. It permitted welding of some alloys not previously satisfactorily resistance welded. There are now more than 60 of these controls operating satisfactorily.

FIG. 1—ONE-HALF CYCLE THYRATRON CONTROL PANEL

3. (The development of thyratron control has been so rapid along with the development of the resistance welding apparatus that the author of the paper probably was not aware of this third development.) Thyratron control is now available for welding in very short periods. For instance ½ cycle, ¼ cycle or less.

The half cycle thyratron control has proved its worth in both the tube manufacturing department of the General Electric Company and in the manufacturing department of the RCA Radiatron Company.

A midwestern manufacturer had a welding machine which apparently was too small for the jobs being done; the welder transformer overheated and the control was a non-synchronous contactor. Thyratron control was applied to this welding machine, with the results that the transformer no longer overheated. The temperature rise was measured and found to be only 15 deg C (with a mechanical contactor the transformer overheated which means that the temperature probably exceeded 60 deg C rise).

There are 3 main reasons why the heating of the welder transformer might be greater if a non-synchronous contactor is used than when thyratron control is used. They are:

1. Where a non-synchronous contactor is used variations in the time of power applications will result. It is necessary to adjust the heat setting of the welding machine so that a satisfactory weld is made when the time element is shortest. This means that when the contactor passes current for longer periods, excessive energy is handled in the welder transformer resulting in heating.

Where thyratron control is used, the welder transformer is adjusted to produce a satisfactory weld for one time setting. The thyratron control accurately times to the same number of electrical cycles for each weld, and therefore no excess heat is handled by the welder transformer.

11—Two invar wires
12—Soft nickel and invar wires
13—Invar and ascaloy wires
14—Ascaloy wire and nickel sheet
15—Ascaloy and hard nickel wires

2. Where a non-synchronously operated contactor is used, relatively long welding times are necessarily used (10 cycles or more), and a large percentage of heat is wasted by radiation and conduction of heat by the electrodes during the time the weld is being made. This results of course, in excess heat or energy being handled by the welder transformer.

Where thyratron control is used the time of power application usually is shortened a great deal, causing the weld to be completed in probably two or three cycles or less, and preventing excessive radiation and conduction of heat away from the weld.

3. With a mechanical contactor, it is entirely probable that the circuit is closed or opened at the zero point of the voltage wave. At the instant the contactor is closed, the flux in the transformer is at practically zero or only of residual value. In the first ¼ cycle, the welding transformer core reaches its full load excitation, and the balance of the first half cycle probably will result in over-saturation of the transformer, resulting in a tremendous current surge, which will be several times full load current (dependent upon the design of the particular transformer). After the transformer core becomes saturated it can no longer transmit the power to the secondary of the transformer. These surges can occur every time the circuit is closed and result in heating the transformer without delivering a proportional amount of power to the weld.

Where thyratron control is used, it is adjusted so that the circuit always is closed at the peak of the voltage wave, resulting in only normal saturation of the welding transformer before the alternating voltage reverses. The result is that stable operation is established from the start and no peak surge of current occurs.

As a result of these findings it has been predicted that resistance welding transformers can be rated higher than previously without increasing the amount of iron, provided thyratron control is used.

The author of the paper has stated in his concluding paragraphs that the resistance welder manufacturers are of course interested in methods of increasing this power factor—which is stated to be between 20 per cent and 70 per cent. It certainly is true that a load of only 20 to 70 per cent power factor is undesirable from a power generation standpoint. Worse than power factor however, is the fact that the load is single phase and intermittent and often causes light flicker. A number of power companies in this country among which are a power company in New Jersey and another in the State of Massachusetts, have insisted upon the manufacturer paying a penalty for this single-phase power, another penalty for the low power factor, and a third penalty for the intermittent operating characteristics. In another location it has been stated that a manufacturer is paying $3,000 premium per month for the privilege of using single-phase power from a public utilities line. This $3,000 is to cover the expense for extra single-phase line and necessary transformers to tie this load in to a high capacity network which runs within several miles of the particular manufacturing plant and to compensate for the unusual power demand.

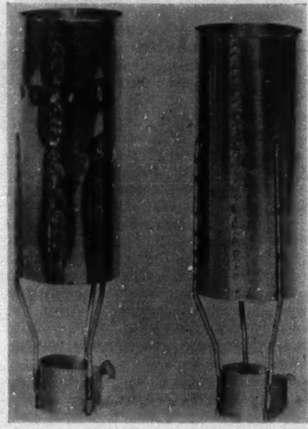

Fig. 3—Special Grid Assembly (Left) Welded On Manually Controlled Welder (Right) Welding in ½ Cycle

All of the above objectionable features or characteristics of the resistance welding load can be overcome by the application of motor-generator sets. More details on this application of motor-generator sets may be found in articles by the writer: "Problem of Power Supply for Resistance Welding," in the December 31, 1932 issue of *Electrical World* and "Balancing Welding Loads on Shop Lines," in the March 1933 issue of *Factory Management and Maintenance.*

**S. T. Maunder:** One point should be emphasized for the benefit of the industry at large. The requirements for secondary voltage and capacity usually are much higher than anticipated. For example, if it is thought that 3 volts are sufficient at the terminals of the weld, then very likely the terminal voltage of the transformer should be close to 10. The capacity is increased in the same proportion. This difference is caused by underestimation of requirements at the weld, larger current flow than was presupposed and too large drop in the terminals or lines to the weld. The drop mainly is due to excessive reactance in the lines, which often is nearly 100 per cent.

It has always been the practice to recommend that adequate tests be made before determining the capacity and voltage of welding transformer equipment.

## RADIO AIDS TO AIR NAVIGATION*

(Green and Becker)

**W. M. Thompson:** The system described in the paper appears adapted particularly for operation over fixed airways, although it appears practicable to use the system when flying toward or away from any suitable transmitting source. This method can be practiced roughly by using almost any aircraft radio direction finder and comparing the bearings with the magnetic compass to obtain the angle of drift when flying a known course but such application lacks the automatic feature of the present development. Actual flights made with only the inductor compass and associated control equipment have demonstrated to certain naval flyers that the automatic steering feature has many desirable attributes as it leaves the pilot with fewer controls to manipulate during flight.

The radio direction finder described as a part of this development appears to incorporate certain novel features but it is subject to certain errors which are inherent in such a system. For example, the output of the direction finder loop indicates a minimum when the plane of the loop is normal to the resulting wave front and such indication may not give the correct bearing unless corrections are applied to compensate for the disturbance caused by the structure of the plane. Propagation phenomena such as the well known "night effect" are encountered which may produce errors or make bearings difficult to obtain. Troubles of this sort can be minimized by using transmissions in that part of the radio frequency spectrum where experience has shown these effects to be a minimum but it is felt that such trouble should be pointed out in order to avoid conveying an impression that perfection has been obtained.

Then operational difficulties attend the use of such delicate devices for in effect a radio direction finder is a sort of bridge which must accurately be balanced if the results are to be accurate. This requires a design where the operating adjustments do not cause a shift in the bearing. The sensitivity must also be sufficient to avoid too much zig-zagging along the desired course.

Similar comments apply to certain forms of range beacons. This is illustrated by the fact that a certain pilot flying a course laid down by a beacon found himself being guided farther and farther to one side of his goal. Subsequent investigation disclosed that the gradual failure of a capacitor in the transmitting equipment caused this shift in bearing. Such an error was only apparent to the pilot by reason of clear weather and knowledge of the territory over which he was flying.

From a naval point of view it might be well to point out that a radio silence by the ships of the fleet probably will be mandatory when the fleet is at sea during wartime and that the only radio available will be that from the large shore stations. Due to the distance of the fleet from these shore radio stations, the possibility of interference is very great.

The above comments are not intended to derogate from the excellent development described to-day, but rather to emphasize the need for intelligent operation of all scientific equipment in light of its capabilities, for defects in such equipment may produce errors at possibly rare intervals which are difficult to detect.

**J. H. Dellinger:** As stated by the authors, the paper is principally on certain new types of equipment, but it gives also an interesting general survey of the whole field. In the fourth paragraph it is stated that radio methods for course and position determination fall under three headings, *viz.*, range-beacons, ground direction finding, and direction finding on the aircraft. For completeness there might be added to this list: directive beacons of other types than range-beacons (*e.g.*, rotating directive beacons), marker beacons, and altitude indicating methods. Of all these methods, there is perhaps the greatest field for development at the present time in direction finding, and it is fortunate that the authors have devoted particular attention to this point. The difficulties of thorough control of phase adjustments under all conditions of operation have retarded past development, and it is noted that this is receiving special attention in the new direction finder.

The following paragraphs summarize the development of a complete system of radio aids for the blind landing of airplanes. This work has been done in research extending over the past four years by the Bureau of Standards serving as the Research Division of the Aeronautics Branch, Department of Commerce. The system described meets all the requirements laid down by Messrs. Green and Becker in the second paragraph of the paper under the heading "Landing Aids." It has recently been demonstrated to the public in a series of completely blind landings under practical operating conditions.

This system gives position in all three dimensions—lateral, longitudinal, and vertical—which is the information that the pilot must have to make a landing. Lateral position is given by a runway localizing beacon, longitudinal position by marker beacons, and vertical position by a landing beam.

Work on this research project was divided into three stages, the first of which consisted of fundamental experiments and research to develop the basic component parts of the system, including the runway localizing beacon, marker beacons, landing beam, and suitable radio receiving and indicating apparatus for use in the air. The second stage consisted of the practical development of these component parts, fitting them together to form a complete system and finally demonstrating the practicability of the system through the medium of an extensive series of hooded landings, conducted by the Aeronautics Branch at its experimental flying field at College Park, Maryland. The third stage of the development, which involves the testing of the complete system experimentally under the conditions obtaining at a commercial airport, is under way at the Newark, N. J., Municipal Airport where the city of Newark has cooperated in the installation of the system.

The work at the Newark Airport includes fog landings as well as hooded landings. The former are, of course, more representative of operating conditions. While the Newark installation is not for service use in air passenger operations, it affords an opportunity for cooperative experimentation with air transport operators.

This system of landing aids is so designed as to require a minimum of special equipment on the airplane and to provide maximum convenience to the pilot. It is an airport system, all of the radio transmitting equipment being located on the ground at an airport. The lateral localizing of the runway is given by a small radio range-beacon of visual type operating on a frequency in the neighborhood of 300 kilocycles. The vertical direction is provided by a landing-beam transmitter operating on about 100,000 kilocycles; this gives a radio beam which is directive in the vertical plane, and marks out a line of equal received intensity in space which is tangent to the ground and suitably curved for the operation of landing. Longitudinal position is furnished by two marker beacons, low-power radio transmitters which give the pilot special signals, one of which he hears as he passes over a point 2,000 feet before the edge of the landing field is reached and the other is heard at the edge of the field.

---

*See page 738.

The pilot hears the marker-beacon signals in his headphones. The indications from the runway localizing beacon and the landing beam are received on a single instrument with two pointers. One pointer is vertical and tells him his position laterally, and the other is horizontal and tells him his position in the vertical plane. By so operating the airplane controls as to keep the two pointers crossed at right angles, like the crosshairs of a gunsight, the pilot keeps the plane on the proper path for landing. When he hears the second marker-beacon signal he levels off and lands. The airplane equipment includes a distance indicator and other auxiliary aids.

Many auxiliary problems have been worked out, such as the coordinating of two-way telephone communication with the other radio devices, and the provision of a monitoring arrangement for the tests of the system. Experiments also have been made to adapt the equipment for use with all wind directions. The runway localizing beacon has been successfully operated in a pit below ground level, thus permitting its use in the center of a landing area. The experience at Newark, however, indicates that in practice it may not be necessary to provide service throughout 360 deg. In the Newark installation the runway localizing beacon and landing-beam transmitter are located northeast of the field, northeast being the direction of the prevailing winds during times of low visability. Both of these transmitters are capable of serving any direction throughout a 45 deg sector, which is sufficient to care for the wind conditions.

**P. V. H. Weems:** When not in sight of known landmarks, there are only two methods of fixing the position of aircraft in flight. We may apply the celestial navigation methods long used by the mariner, or else we may utilize the directional characteristics of radio waves. Celestial navigation is not available in fog, while on the other hand, it is a relatively simple and inexpensive method wholly self-contained, that is, it requires no cooperation of equipment or personnel outside the plane. Radio is independent of fog or other low visibility, but it does require assistance from equipment and personnel outside the plane. Furthermore, radio equipment is relatively expensive and complicated.

The most promising feature of radio navigation is the fact that so much has been accomplished in such a short time. Radio is a new art. In fact, most of us have grown up with it. With so much progress made in such a short time, it is logical to assume that another decade will result in the simplification and improvement of radio aids to air navigation to the point where it will be indispensable and almost universally used.

The science of air navigation is an extensive and difficult subject. The future will require navigation specialists who devote full time to the subject. In fact, during the development stage, full time may be devoted to radio alone to good advantage. Regardless of the preferred method, one fact must be kept in mind, *we should use all means available for the safe navigation of aircraft.* This includes dead reckoning, radio, and celestial navigation. The remainder of this discussion is restricted to radio; those interested in the other two methods are referred to "Air Navigation," (McGraw-Hill) for details.

Aside from its value for rapid communication in flight, radio navigation equipment is becoming standard equipment for planes in scheduled passenger flight. The widest use for radio for navigation purposes is found in the simple course indicators for use with the airway beacons on established airways. There are various types; aural, visual, or a combination. Also, the direction finder may be located either in the plane or on the ground. The details of these devices are explained in detail by the Department of Commerce "Air Commerce Bulletin," or by literature furnished by the manufacturers.

The ultimate goal of the air navigator is an automatic radio "super-metal mike" which will steer a plane continuously on its direct course regardless of wind drift. Such a device is the G-E automatic steering control with automatic radio drift correction. The writer was privileged to see two impressive demonstrations of this equipment. While the details of this equipment are in the development stage, the basic principles are definitely established. It should now merely be a question of time, intensity of demand, and the generous backing of the government, before a plane can take off and fly surely in a direct line to any desired point merely by grinding in the "address" of the destination. The address is given in the form of the course to be steered which is set for the automatic steering device. The plane will then take up a course at an angle to the true course equal to the wind drift and "crab" in a direct line to the destination. The latter part of the paper gives the details of this device and in Fig. 8 illustrates the demonstration equipment. In the writer's opinion it is difficult to over-estimate the value of this development to future aviation. With the simple addition of means for observing bearings received from a second station, the air navigator is enabled not only to proceed direct to his destination, but he may also determine his progress along the course at will.

The research necessary for the development of this and other equipment is expensive, and can only be carried out by the government or by large corporations such as the General Electric Company. The government should back the efforts of the General Electric and other firms by placing orders for the finished product, and by giving prizes for methods and equipment meeting the required rigid specifications.

**C. F. Green:** Three comments coming from Commander Thompson's discussion should be noted:

The metal structure of an airplane introduces errors in the compass bearings obtained with radio, which are comparable with those obtained on the magnetic compass. These can be compensated for in much the same way either by using a correction card or a correction cam in the controller circuit.

Errors obtained by a shift in apparent direction of wave propagation caused by interference of the reflected wave have to date been corrected only by special receiving and transmitting loops. It is believed that this method will be perfected so that accurate bearings may be obtained 24 hours of the day.

The value of radio compasses in war time will depend a great deal on the particular countries engaged. During the last war the high power low frequency stations, such as New Brunswick, N. J., Nauen, Germany, Bordeaux, France, and Carnarvon, Wales, worked almost continuously, and in Europe it would be rather difficult consistently to blanket out these stations. Any broad interfering wave transmitted to cause interference would have very little range.

Doctor Dellinger's timely short description of the system now undergoing tests at Newark, N. J., is of special interest since it is the result of extended work. The authors agree heartily with Commander Weems in his italicized words, not only in regard to navigation but also concerning other matters contributing to safety in flight.

# Radio Aids to Air Navigation

BY C. F. GREEN* and H. I. BECKER*
Associate A.I.E.E. Non-member

IT IS considered advisable to state in introducing this paper that its principal subject matter covers equipment which is believed to embody new and interesting features, but that refinement in detail and further testing are still necessary to reduce it for service. If so reduced its adoption will depend on its ability to compete with other systems of navigation from the standpoint of application, accuracy, simplicity, reliability, weight, size, and cost.

Radio has played an outstanding part in the promotion and maintenance of regular scheduled flight and safety in air transportation. In a relatively short time it has become an essential means of communication and navigation, and is steadily increasing the number and extent of its applications. It is particularly useful because it furnishes the navigator with reference axes and points.

One- and two-way communication have placed at the disposal of the pilot: weather information at points along the route, traffic conditions on the airway and at the terminals, assistance in case of trouble, and in isolated cases almost the sole means of effecting a landing in low fog at the terminal airport. Stations along the federal airways, installed and maintained by the Airways Division of the U.S. Department of Commerce, give weather information collected from 93 weather stations by teletype, while stations of the individual operators handle dispatching, traffic direction, and related matters.

In general, radio methods for course and position determination fall under three headings: (1) range beacons, (2) direction finding of aircraft position by ground stations, and (3) direction finding on the aircraft itself.

In the United States the first has been employed almost exclusively. The Department of Commerce has installed two types of radio range beacon stations along the federal airways of the country. The aural type making use of code signals indicates, by the interlocking of the "dash-dot" and "dot-dash" into one long dash, that the plane is on the course; periodic station-identifying code letters indicate the course followed. The visual type employing two modulation frequencies and a tuned reed indicator shows flight along the course by equal amplitude of reed vibration. Both systems have been described in much detail in various journals.[1,2,3,4,5] The aural range beacons have been in use since the establishment of the airways, while developmental visual stations have now led to the construction of a considerable number of this type. Continual progress is being made in these services, resulting in such improvements as simultaneous telephone and range beacons, T-L antenna system to overcome "night effect," and the reed converter for visual indication.

Directive beacons, with the straight airway between them, are supplemented by small marker beacons at intervals along the route. These low-power transmitters, giving a characteristic signal, serve to indicate position along the airway.

Here, then, is a system of communication, a system of navigation along fixed routes, and means of getting approximate position on the route, which have been of inestimable value.

Navigation along independent routes requires direction and position finding either (1) on the ground with transmission to the aircraft as in use on the airways of Europe or (2) on the aircraft by direction finder or compass. In the former, ground direction-finding stations triangulate on the characteristic radio signal of the plane and, having determined the craft's position by combining their individual readings, transmit it to the plane. This system has the disadvantages that the indications are not continuous and that the position indicated is that occupied by the plane some time previous.

Direction finders based on minimum signal employing loops aboard the craft are in extensive use on marine vessels, lighter-than-air craft, and also to some extent on airplanes. This equipment makes possible the fixing of position by triangulation, and guidance along a route toward or away from a transmitting station by maintaining the indication at the minimum; but it does not show that a deviation is to the right or left of the course. A radio compass makes possible direction finding and gives right and left indication of deviations from the course.

## RADIO COMPASS

An ideal radio compass for use in controlling the course of an aircraft would be one that would give right and left indications on both continuous and modulated wave radio signals sensitive around the zero position, and not destroy the characteristics of the signals used in communication.

Radio compasses have been in use for years along the coast to determine the position of ships. In these installations loop antennas are used to get the line between the ground station and the ship, but the loop alone does not tell at which end of the line the ship is located except, of course, that on the east coast the ship naturally will be to the east of the station. In order to determine from which end of the line the signal is coming it is necessary to compare the output of the loop antenna with the output of a vertical wire antenna. This is done by combining the two outputs and noting the effect in head phones when the loop is swung from one side of zero to the other.

A radio compass for use on aircraft must give right and left indications on a visual indicator so that if the pilot when flying toward a radio station turns the

---

1. 2. 3. . . . See bibliography at the end of article.

*Presented at the North Eastern District Meeting of the A.I.E.E., Schenectady, N. Y., May 10–12, 1933.*

ship to the right, the indicator must turn to the right; if he is flying on a course away from the radio station and the ship is turned to the right, the indicator must show left, indicating that he is flying away from the radio station. Several radio compasses have been developed to give these indications. In general these contain some form of a synchronized switching device which rapidly switches the polarity of the loop with respect to the vertical antenna and at the same time switches the rectified audio frequency output using a zero-center indicating device; this gives a sense of direction if the loop increases the voltage picked up on the vertical antenna when connected for right indication, and bucks when the indicator is connected for left indication. This principle gives fairly satisfactory results, but it destroys the characteristic of the signal for use in communication and the accuracy is effected by phase-angle shifts in the radio receiver due to any regeneration that might be present.

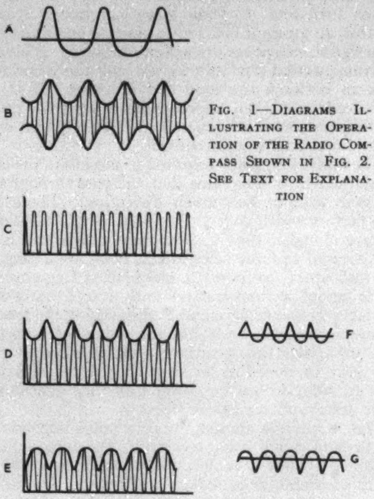

Fig. 1—Diagrams Illustrating the Operation of the Radio Compass Shown in Fig. 2. See Text for Explanation

A radio compass utilizing an entirely different principle has been under development; it does not depend on synchronizing the input and output of the radio receiver, and it does not destroy the modulation that might be present on the radio signal.

A loop antenna has directional characteristics in that the voltage induced in it becomes a minimum when the loop is normal to the direction of the radio wave, whereas a vertical wire antenna has no directional characteristic to waves approaching in a horizontal plane. Also the polarity of the loop with respect to the vertical wire antenna can be reversed by rotation; thus it is possible to use the voltage from the loop to buck or boost the voltage induced in a vertical wire.

The foregoing describes a method of indicating when the loop is not normal to the direction of propagation of the radio wave and also to which side it is turned. The next step is to transform the combined radio frequency energy from the loop and vertical wire to direct current which will reverse when the loop is turned from the bucking to the boosting position. This is accomplished by modulating the output of the loop with an audio frequency having a wave form as shown in Fig. 1*A*. This wave form is maintained through the radio receiver and audio output to a non-linear resistor in series with the visual indicator. A non-linear resistor is one in which the current does not change in proportion to the applied voltage; thus if an alternating current having a wave form as in Fig. 1*A* is applied to the resistor, the polarity of the wave having the highest peak value will cause more current to flow than the opposite polarity even though the rms values of both sides be the same. This increase in current from one side of the wave causes an indication in the d-c indicator and if the alternating current be reversed the indication will be reversed. Turning the radio loop from its zero position to one side or the other causes the peak side of the audio frequency output of the receiver to appear on one side of the wave or the other.

In Fig. 1*B* is shown the radio frequency envelope of output from the loop, which does not appear except when the loop is turned off normal; this is combined with the steady wave Fig. 1*C* from the vertical antenna. Figure 1*D* shows the resultant when the loop is turned in the proper direction to cause its voltage to add to that in the vertical antenna, and Fig. 1*E* shows the resultant when the two voltages are bucking. Figures 1*F* and 1*G* show the resultant a-c rectified currents from the radio receiver detector. When the aircraft is on its course, the radio loop is normal to the radio wave and the voltage across it is a minimum. Therefore there is no effect of the compass attachment transmitted to the receiver and

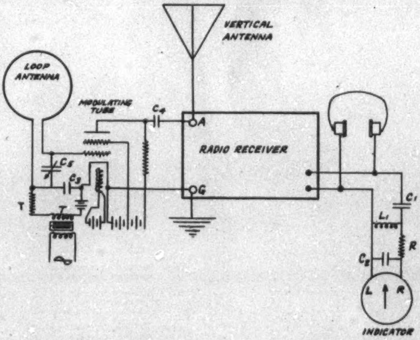

Fig. 2—Schematic Diagram of Radio Compass for Air Navigation

head phones, thus allowing the receiver to be used for communication purposes.

Referring to the schematic diagram, Fig. 2, the compass effect is transmitted through condenser $C_4$ to the antenna binding post of the receiver, and the audio frequency output is connected directly to the head phones and indicating system. Condenser $C_1$ and inductor $L_1$ are used to prevent excessive voice modulation from appearing on the indicator; $R$ is the non-linear resistor and $C_2$ is a smoothing condenser. The wave shape Fig. 1 is obtained by the action of resistor $R$, and the grid current in the modulating tube; this wave shape can be duplicated by combining the fundamental and second harmonic in the proper amplitude ratio and phase angle difference. Thus it is possible to modulate the loop energy with an audio frequency $f$ and combine it with a $2f$ frequency at the non-linear resistor; but any shift in phase relation caused by a delayed action in the radio receiver would tend to make the indication insensitive, or if carried too far the indicator would show reversed directions. This difficulty is a common experience with the type of compass that depends on the synchronized switching between the radio receiver input and output circuits, and prevents the use of any form of regeneration. With the compass just described, regeneration up to the point of oscillation does not interfere with the accuracy of the compass attachment—in fact when the receiver is oscillating as used for continuous wave telegraph reception compass bearings can be obtained, but the sensitivity of the overall system is considerably reduced because of the overload on the detector stage.

FIG. 3—DIAGRAM SHOWING DRIFT OF AN AIRPLANE FROM A STRAIGHT LINE COURSE CAUSED BY WIND

Receivers equipped with automatic volume control can be used with this compass because such control not only automatically increases the amplitude of the combined signal from the radio loop and vertical antenna, but also maintains the ratio between the $f$ and $2f$ frequency in the audio output circuit. Referring to Fig. 1 it may be noted that the average values of the radio frequency current when the loop voltage adds to that from the antenna (Fig. 1*D* and *F*) is higher than when it opposes (Fig. 1*E* and *G*). This causes a shift in the operating level at the detector tube and if, when using automatic volume control, an attempt is made to operate on too powerful a signal, erratic results will be obtained. This can be compensated partially by varying the respective pick-up between the loop and antenna. It is experienced only when approaching a powerful transmitting antenna and generally is not required with a hand operated volume control.

The audio frequency required to modulate the loop output can be of any value that will pass through the receiver without too much distortion. There are two factors which govern the frequency: if the frequency is higher than 1,500 cycles, a high-pass filter can be used to limit voice effects from appearing on the indicator; because the modulating frequency is made up of a fundamental and second harmonic, the receiver should be capable of handling the second harmonic frequency without too much transmission loss, otherwise the sensitivity will be affected. It also may be desirable to keep the frequency fairly high in order to use the lower range for continuous wave telegraph reception.

The sensitivity around the zero point depends on the type of signal being received. On unmodulated continuous wave stations it is a maximum, and on badly overmodulated waves a minimum, averaging approximately 10 deg for full scale deflection daylight reception on broadcast stations 150 miles away. By using head phones directions can be obtained down to a fraction of a degree.

The distance range of the compass attachment is limited to that of the radio receiver with which it is operated; in general it will give satisfactory bearings on broadcast stations that can be received loud enough for ordinary loud-speaker operation or, in reception on aircraft, the range is about the same as that obtainable for head phone reception. Rough bearings can be obtained in bad static conditions when telephone reception is impractical.

With a satisfactory radio compass it becomes possible to navigate an aircraft with much greater accuracy, with a resultant saving in fuel; it permits night expeditions over strange territory or water; it is valuable in photographing; when one is lost it becomes useful in obtaining angles for triangulation; and when combined with a magnetic compass it presents a system of navigation which automatically corrects for wind drift.

## COMBINATION OF RADIO COMPASS AND MAGNETIC COMPASS

Referring to Fig. 3, if one wishes to fly from Washington, D. C., to Schenectady, N. Y., and maintain his course by following a magnetic compass with a west wind blowing he would travel a course

*AB* to the east, never arriving in Schenectady. If he tuned in radio station WGY and flew according to the radio compass the course would be along *AEF* eventually arriving but traveling a considerable distance out of his way. Referring to Fig. 4 it may be noted that angle *a* between the magnetic north and the course remains constant whereas if the craft should drift to the left, for instance, it might still be headed for its destination by following the radio compass but the angle with respect to the north pole would become *b*. Thus in order to maintain both the magnetic angle and the radio compass satisfied, it is necessary to keep on a straight line course to the destination.

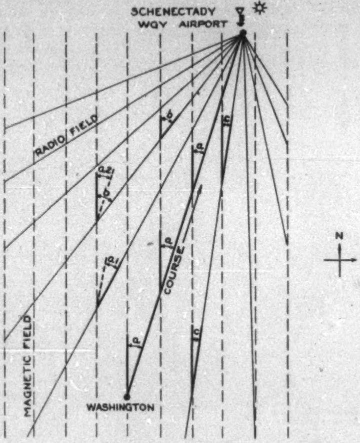

Fig. 4—Diagram Showing How an Airplane Is Held to Its Course by Combining Radio, Magnetic, and Gyro Units in a Compass System

The following system to accomplish correction for drift will operate with any type of compass, but tests have been made with the magneto compass, hence a brief description of this instrument is given. It is essentially a small d-c generator (Fig. 5) which depends on the earth's magnetic field for excitation and obtains its rotating power either from a 12-volt motor or a wind driven impeller. In order to collect a maximum of magnetic flux for the field, permalloy poles are used. A sensitive center-scale ammeter is used for the indicator and the indication becomes zero when the poles are in the east-west position. The instant the poles are turned away from this position a magnetic field is established across the armature causing a voltage to be generated and an indication on the indicator, the direction depending upon which way the flux travels through the poles.

There is a remote control or course-setter which enables the poles to be rotated to a position which will be east and west when the aircraft is on its proper course. The output of the compass generator also can be used to operate a sensitive polarized relay which in turn can be used to operate an automatic steering engine, Fig. 6. This engine is driven by a 12-volt motor which rotates the steering drum in either direction by the use of electrically operated clutches. The clutches are controlled by the magneto compass and the overall system is stabilized by a follow-up system which introduces a counter emf in the compass circuit eventually becoming equal and opposite in polarity to the current generated by the compass. The follow-up device is operated directly from the steering drum and permits the rudder to be turned an amount proportional to the current from the compass. It also causes the rudder to return to its mid-position without overshooting.

Referring to Fig. 7 it may be noted that in order to maintain a straight course between the starting point and the destination, it is necessary to maintain the radio compass loop $L_1$ $L_2$ normal to the course and the magnetic compass poles $P_1$ $P_2$ east and west. If the aircraft be permitted to drift to position *B* and the angles of both compasses are not changed, then it may be seen that the radio loop is no longer normal to the radio station or course; and if the output of the radio compass was used to control the rudder, the craft would make a left turn toward the straight line course.

In order to make this correction automatic it is necessary to operate the compass pole rotating mechanism with a motor and also to permit the loop to be rotated. Figure 8 shows a test stand equipped with the developmental equipment. The steering engine here differs somewhat from the one previously shown in that it contains an extra set of clutches and a differential gear box, the drum on top of the engine

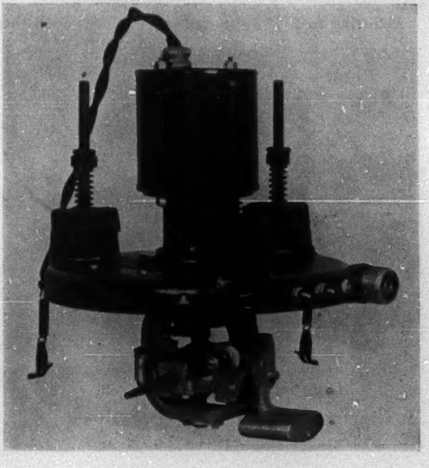

Fig. 5—A Motor Driven Magneto Compass Generator With Cover Removed

having a small metal rudder which represents the rudder of an aircraft. The control panel is arranged so that the rudder can be operated directly by either the magneto compass, the radio compass, or the combination of the two which gives automatic drift correction. When switched for drift correction the magneto compass poles are automatically kept in an east-west position by using the output of the compass to control the second clutch assembly; this in turn rotates the poles until the compass output is zero. Attached to this clutch mechanism is a differential gear box which is connected mechanically to the rotating mechanism of the radio loop. The differential gear box permits the angle between the radio compass and the magneto compass to be set and after that no matter which way the aircraft is turned the two compasses will remain at a fixed angle with respect to the magnetic north pole.

The output of the radio compass controls the rudder and thus the craft is directed according to the angle set up between the two compasses. To correct for wind effects the craft will automatically assume a heading or "crab" into the wind a sufficient amount to maintain its course on a straight line. If the wind increases or decreases the "crabbing" angle will automatically change.

The gyro turn compensator is used to stabilize the system in rough weather and when making rapid turns, although the equipment is intended for use only for fairly long level flights and not for rapid maneuvers.

Referring to Fig. 8 showing the control panel, the course setter to the right is used to set the angle of the course and the indicator to the left shows the actual heading of the aircraft. By subtracting the two angles the difference indicates the angle of crab and is a direct indication of the effect of the wind.

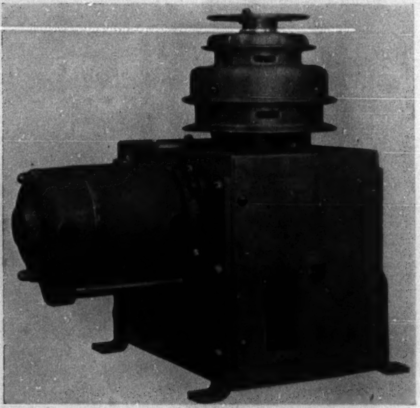

Fig. 6—Developmental Aircraft Rudder Engine for Automatic Steering, With Dynamotor

After establishing the ability of maintaining a straight course and the angle of crab, it remains necessary only to determine ground speed to determine the exact location during the flight. This may be determined by orienting the loop on a second radio transmitting station.

Using test equipment a plane has been automatically steered to destination with correction for drift by the described method, but work remains to be done to reduce the equipment to service form.

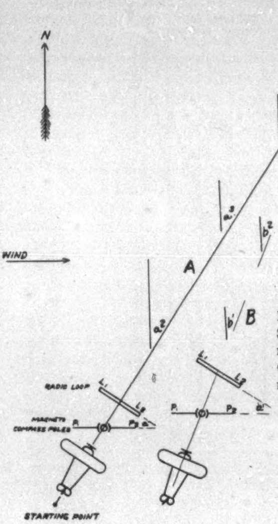

Fig. 7—Diagram Showing How an Airplane Is Held to Its Course by a Combined Radio and Magnetic Compass

## Landing Aids

The safe landing of aircraft during adverse weather conditions remains the great problem confronting air transportation. In general, transport companies avoid any possibility of being caught in a position where it is necessary to attempt a landing in fog, in the same way that all ocean liners meet their corresponding problem. However, several organizations are now making strenuous efforts to solve this problem. Here it is that all the agencies are to be investigated, radio, sound, light, and any others, for each may contribute to the solution.

The landing of planes at an airport under blind flight conditions requires the guidance of the plane from the beacon course or the course determined by radio compass to an approach course at the airport, the determination of runway position, knowledge of height above ground and traffic conditions about the port.

Several methods have been proposed and demonstrated, including the Guggenheim Fund work of Major Doolittle, the short-wave radio beam developed by the Aeronautics Research Division of the

Department of Commerce at the U.S. Bureau of Standards, the system developed at Wright Field by Captain Hegenberger, and others. As in other flight equipment, it is desirable to limit the total apparatus, particularly that on the plane, to a minimum, and to make use as far as possible of instruments that are needed for normal flights or that become an aid in emergency landings. Thus the relocation of those range beacon transmitters situated near an airport such that one of the radiating courses lies across the airport as now planned by the airways division will assist the pilot, and the use of available receiving equipment aboard the plane without duplication serves to reduce the carried weight to a minimum.

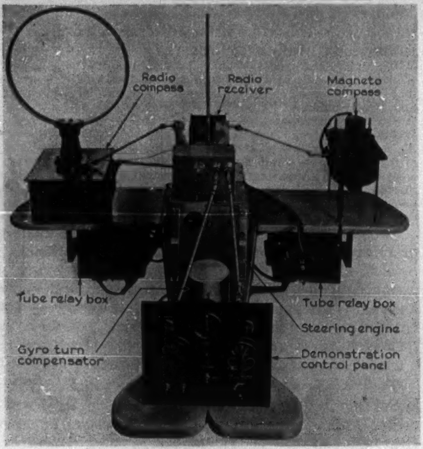

Fig. 8—Experimental Automatic Steering Control With Automatic Radio Drift Correction, Mounted on a Test Stand

A few portable runway-localizing beacons have been constructed which have outputs of from 10 to 15 watts. These use small cross loop antennas so located that the vertical plane containing the axis of the desired runway bisects the angle between the two loops. These beacons are essentially the same as the radio range beacons mentioned previously except smaller in size and output.

The range of the localizer transmitters is from 7 to 15 miles so that a plane may be brought in from a distant range beacon course to the desired runway. It is desirable that the set be adapted to voice modulation, thus placing the operator in telephone communication with the pilot at any time.

The localizing beacon can be used with several types of supplementary aids. Airport boundary marking may be effected by radio or sonic markers each throwing out a barrage through which the plane, in passing, receives an aural or visual indication. The indication of height above ground may be determined by a sensitive barometric altimeter or by a sonic altimeter. The first gives approximate comparative heights which do not follow the contour of the terrain while the sonic altimeter, described elsewhere,[6,7] permits the pilot to know his height during the glide over adjacent ground, the time at which he passes the boundary, providing the sonic type of boundary marker is used, and the gradual approach to the surface of the runway in normal gliding position thus eliminating the necessity for a shock landing. The sonic altimeter likewise is effective in emergency landings.

It is not yet apparent what the ultimate system or systems will be, but whatever leads to successful operation will lean heavily upon radio aids. Tests conducted to date with the equipment described in this paper show results indicative of material aid in the solution of problems of flight.

## Discussion

For discussion of this paper see page 736.

# Reactive Power Concepts in Need of Clarification

BY ARCHER E. KNOWLTON*

Fellow A.I.E.E.

***Synopsis.**—To assist in clarifying the present concepts of reactive power, the following introduction to the subject has been prepared. An analysis of the reactive conventions made by Doctor Silsbee, a member of the subcommittee, is included.*

IF ALL electrical iron could by divine decree or presidential proclamation be straightened into uniform permeability over its whole range of magnetization there would be less occasion to raise the question of adequacy of our prevailing concepts of reactive power and power factor. If all synchronous machine windings under all conditions of loading could have flux distribution in strict conformity with symmetrical sinusoidal generation there would be still less. Moreover, the excuse would nearly vanish if polyphase circuits could always be held to rigid balance of impedances on their lines and loads. With these factors eliminated the residue of doubt, if any, would be a topic to intrigue only the academic and metaphysical minds.

But no one of these 3 ideals is attained fully in practice and the degree of departure in any particular instance is what justifies an effort to take some of the slack out of the power factor and reactive concepts. However, power factor is only a ratio expressing the interrelations between true power, apparent power, and reactive power. The focus is at once upon reactive power because of the 3 aspects of energy flow, it has been given second place in analysis and measurement.

The quadrature component accompanying energy flow in inductive and capacitive circuits has vagaries which, relatively speaking, have been overlooked while energy, power, voltage, and current were being explored and reduced to systematic and conventional procedure. During the last 5 years there has been a growing disposition in academic circles to turn the mathematical weapons concertedly upon the reactive constituent. To Prof. Constantin D. Busila of the Polytechnic School at Bucharest, Roumania, and Roumanian representative on the International Electrotechnical Commission, is given most of the credit for bringing the loose status of flux-energy to the fore. At the International Conference on High-Voltage Electric Systems (Paris, 1927), Professor Busila presented a paper, "The Power Factor and Its Improvement." Discussion of it disclosed such differences of opinion on the basic phenomena that a special advisory committee was formed under Roumanian sponsorship. Out of it came the Roumanian "Questionnaire on the Problem of Reactive Power" which was given international circulation.

No categorical answer to that questionnaire has been given by the A.I.E.E. A special subcommittee* was constituted by the standards committee to prepare an answer. In 1931 the only answer that could even partially be agreed upon as a suggestion to the standards committee for transmission to the Roumanian committee was that:

> "... prevailing methods of measuring reactive components are acceptable as a practical expediency, although it is recognized that errors of measurement are incurred under unbalanced and non-sinusoidal conditions. However, the relative unimportance, from the economic standpoint, of reactive power flow as compared with demand and energy elements of electricity costs tends to discount the value of an exhaustive and abstract analysis of the inconsistencies of reactive concepts and the corresponding technique of measurement. In brief, American practice is content with the definition of reactive component as that quantity which is measured when the potential is shifted to quadrature with its appropriate vector position for true power measurement.

Such an answer at the most appears to be evasive or temporary and not erudite or graced with much professional courtesy. The committee set about assembling the foundation for a more comprehensive answer. The symposium on reactive power at the Institute's North Eastern District meeting in Schenectady, May 10–12, 1933, is one result and is a major phase of the subcommittee's activity.

That is the history. Now why so much concern about a circuit manifestation that is always subordinate to the energy and power objectives of practical operation? It is condoned and tolerated, manipulated subserviently, by some viewed merely as the source of power-factor characteristics, by others as merely something to be metered as simply as possible. But the Institute owes to the profession the reduction of the quadrature component to the same degree of specificity as has been done with the true power and energy. Otherwise there can be no rigid definition of power factor (we have one now but it is admittedly not the whole and final answer). In fact the whole uncertainty about reactive power could readily be exaggerated to the point where power factor would have to sacrifice its present abode among the élite definitions (like those of energy, potential, capacitance, etc.) and move into a more plebeian neighborhood (among diversity factor, load factor, use factor, etc.). Some of the queries raised about the quadrature component must, unless it is reduced to systematic treatment, lead to that result for all persons who think occasionally of circuits other than those permanently balanced and subjected only to sinusoidal currents and sinusoidal voltages.

Energy in transit in an electrical system can perhaps be likened to an army on the march over varied terrain. The ideal would be an accelerated and synchronized movement of all branches up to noon and a decelerated movement toward nightfall and encampment—smooth progress "all above the line" like the instantaneous progress of energy in a non-reactive circuit. But actually the tired and ponderous units "lag" and delay the procession when the going meets obstacles. Light and eager units "lead" the rush when there are vacant and alluring tarrying points ahead. Most of the army ultimately gets to its destination and is potentially useful on arrival but the route and the terminal bring out the mobility idiosyncrasies of heavy tanks and fast motor units, speedy cavalry, and sluggish infantry. The laws of the mass movement are relatively simple but the laws of the out-of-phase movements are a bit intricate. Inject the rearward movement of units back to the base for refreshment and recoupment and the picture becomes more complete and more intricate. What is the "power factor" of such a system? What would it be for a complete military force embracing 3 armies moving in parallel to a common objective?

---

*Chairman, A.I.E.E. Subcommittee on Reactive Power.

This article serves as an introduction to the reactive power symposium held during the Institute's North Eastern District Meeting, Schenectady, N. Y., May 10–12, 1933.

* Subcommittee on reactive power: Vannevar Bush, A. L. Cook, W. B. Kouwenhoven, F. A. Laws, P. MacGahan, F. V. Magalhaes, E. J. Rutan, F. B. Silsbee, and A. E. Knowlton, *chairman.*

To make the presentation more specific in electrotechnical terms here are a few of the vagaries, occasionally stated categorically but in fact subject to argument and, at present, opinion. The author disclaims any intention to take sides on any point. The intent of this introduction and of the Schenectady symposium is to elicit all viewpoints with the hope of clarifying the issue and making progress toward conventional handling of the concepts, the terminology, the symbolism, the metering, and the economic application of the reactive component of energy flow. The following are largely paraphrased from the Roumanian Questionnaire.

1. Reactive power is not conserved in exchanges between circuits of different frequency (rotor and stator of induction motor, for example.)

2. Reactive power to some may present a paradoxical tendency to change sign when the phase-sequence or alternator rotation is reversed.

3. For some, reactive power is distinct from the mean intrinsic energy localized in the electric and magnetic flux fields.

4. Some apparently attribute to reactive power only that degree of reality that attends the circulation or oscillation of intrinsic energy between the reactive receiving devices and the transmitting network.

5. Since (4) leads to a mean value of zero for the instantaneous condition of the interchanges, some hold that reactive power is wholly fictitious and has no reality.

6. Even though the accepted labelling of reactive power as $V \sin \varphi$ is identical with $2\omega(W_L - W_C)$, that is, twice $2\pi f$ times the net difference between instantaneous magnetic and electrostatic energies, for sinusoidal conditions, what will be taken for $f$ where non-sinusoidal conditions arise from a superposition of frequencies?

7. The preceding items indicate the necessity of establishing the degrees of reality and fictitiousness which shall be assigned to reactive power.

8. Until this is done there remains an element of uncertainty in the following commonplace relationships for all but the ideal transfers of energy in which volts, amperes, and watts hold to strictly sinusoidal behavior:

$$\begin{aligned} P &= EI \cos \varphi \\ Q &= EI \sin \varphi \\ EI &= \sqrt{P^2 + Q^2} \end{aligned}$$

9. With equal doubt therefore about $Q$ and $\varphi$ there is a geometrical uncertainty in the vector diagrams which represent the effective values of non-sinusoidal quantities or the single-phase equivalents of unbalanced polyphase quantities. The conventional way of finding the sinusoidal equivalent of non-sinusoidal quantities meets the requirements of true power but introduces inconsistencies with regard to the out-of-phase manifestations.

10. The rising reversion to d-c by way of rectification devices brings non-sinusoidal manifestation to the fore and thus accentuates the need for elevating reactive concepts toward parity with the true-power concepts.

11. Substitution of equivalent sinusoids suffices for power treatment but, since the proportioning of the harmonics affects the reactive quantity, the equivalent sinusoids are not wholly determinative for the reactive quantity.

12. Reciprocal deformation effects between current and voltage occasion cross-product terms in the expansion of a power expression which cancel in the final summation for delivered power but they do not cancel correspondingly in the reactive expression.

13. It appears that a deformation factor may be needed to rid the reactive component of its uncertainty under non-sinusoidal conditions or else a term for "deformation power" introduced as a correction. One suggestion (Liénard) has been that "apparent power is equal to the maximum of the values which the active power can take when we modify in all possible manners the form of the current and that of the applied voltage, the effective values of these voltages and currents remaining fixed."

14. In some quarters "reactive factor" (reactive power divided by real power) is coming into use and approaching sanction. It will inherit the same weakness as power factor.

Those are the elements of the problem. The incidence of these areas of doubtful status upon the electric system seems to fall primarily into certain categories. First, there is the mathematical approach to ascertain the degree of reality to be assigned to the quadrature component. This is treated from the abstract point of view by Professor W. V. Lyon in his paper, "Reactive Power and Power-Factor." Second, there is the analysis of the non-conservative attribute of reactive power when viewed from the standpoint of the mesh which constitutes the practical system of power transmission; Professor V. G. Smith's paper, "Reactive and Fictitious Power," is on this topic. Third, the technique of symmetrical coördinates could well be applied to this subject to ascertain how much conversion to balanced systems would be helpful in reducing the uncertainties; this C. L. Fortescue has done in his paper, "Power, Reactive Volt-Amperes, Power-Factor." Fourth, power system operators have come to look upon the reactive component as a quantity to be dispatched more or less independently of the true power. About it has grown a technique which should be correlated with the academic analysis; one practice in this respect is presented by J. A. Johnson in his paper, "Operating Aspects of Reactive Power." Fifth, the meter technician has a point of view on this matter because in the final analysis it is his task to meter reactive component in conformity with the standards and conventions. W. H. Pratt expresses this point of view in his paper, "Notes on the Measurement of Reactive Volt-Amperes."

More or less distinct from the foregoing is a call to establish a conventional procedure in representing the reactive component in power triangles. Practice is about evenly divided. Some engineers and writers habitually or advisedly draw lagging reactive component vertically upward and some draw it downward from the right-hand end of the kilowatt base. A leading component is of course given the reverse direction by the 2 schools of thought and practice. Misinterpretation is manifestly possible under such divergent practice where the author assumes that the reader belongs to his own camp and therefore fails to label his diagrams specifically.

This confusion was referred to the subcommittee by the standards committee so that the United States national committee of the International Electrotechnical Commission may be enabled to recommend through Prof. A. E. Kennelly to the committee on electromagnetic and magnetic units, the conventional treatment preferred by the A.I.E.E. A ballot mailed to 75 actively interested members of the Institute brought response from 50 but there was not a strong preponderance for either standard. The most comprehensive reply was submitted by Dr. F. B. Silsbee, a member of the subcommittee. He advocates standardizing inductive kilovars as positive and capacitive kilovars as negative in power triangles.

With no intention of influencing any one who may wish to contribute his preference for the committee's guidance but merely because it displays admirably the factors upon which a decision could be based on analytical grounds as contrasted with the habitual, the presentation of Dr. Silsbee is incorporated herewith. The committee will welcome letters from Institute members who read this and, because of it or in spite of it, hope to see a particular geometrical direction assigned to reactive power of the inductive and capacitive forms when represented with power and volt-amperes in power triangles. Dr. Silsbee's presentation follows:

## ALTERNATIVE PROCESSES FOR DEFINING THE SIGN OF REACTIVE VOLT-AMPERES

The following general principles may be set up as governing the adoption of scientific conventions as to the signs of electrical quantities:

1. Positive real quantities are drawn to the right, and positive imaginary quantities are drawn upward.

2. A resultant effect is the (complex) sum of its components. Thus if $c$ is the resultant of $a$ and $jb$, we write $c = a + jb$ and draw $b$ upward.

3. By the rules of complex algebra $d$, the reciprocal of $c$ is given by

$$d = \frac{1}{c} = \frac{1}{a + jb} = \frac{a}{a^2 + b^2} - \frac{jb}{a^2 + b^2}$$

4. The unnecessary introduction of negatives in fundamental definitions is to be avoided.

Of the foregoing statements, 1, 2, and 3 are part of our fundamental mathematical notation and are now so universally accepted as to stand unchallenged. Statement 4 is a more philosophical point but of generally recognized weight.

Confining our attention to sinusoidal current $I$ and voltage $E$ we have

5. $R = P/I^2$, $P$ being the real power.

6. $X = \omega L - \frac{}{\omega C}$

7. $Z = R + jX.$

8. The phase angle of the impedance is $\theta_z = \tan^{-1}\frac{X}{R}.$

The sign of $X$ is the result of a purely arbitrary choice, made so long ago that there seems little need, or hope, of changing it. Eq 7 indicates that impedance is the resultant of resistance and reactance in the sense of principle 2.

We also have the definition

9. $Y = \frac{1}{Z}$

which by principle 3 leads to

10. $Y = \frac{R}{Z^2} - \frac{jX}{Z^2}$

and as an abbreviation we define the conductance

11. $G = \frac{R}{Z^2}$

All of the relations to this point follow from the arbitrary principle 6, with no violation of any of the first 4 principles. In the definitions of susceptance, $B$, however, 2 alternatives present themselves. One of these, which is that generally used (certainly in the United States) will be designated in Table I as **I**; while the opposite, which will be designated by **II**, has been urged by some. The inherent difficulty from the minus sign in 3 is met in a different fashion in the 2 conventions and neither is all that could be desired.

Of the alternatives in Table I it will be seen that **IBa** is the only.

**Table I—Alternative Conventions**

<table>
<tr><td colspan="4">I*</td><td colspan="4">II*</td></tr>
<tr><td colspan="4">12. $B = +\frac{X}{Z^2}$<br>Thus satisfying 4<br>Whence<br>13. $Y = G - jB$<br>violating 2; or stating that $Y$ is not the resultant of $G$ and $B$.<br>The phase angle of admittance is<br>14. $\theta_Y = \tan^{-1}\frac{(-B)}{G} = -\theta_Z$</td><td colspan="4">$B = -\frac{X}{Z^2}$<br>violating 4<br>Whence<br>13. $Y = G + jB$<br>thus satisfying 2<br>The phase angle of admittance is<br>14. $\theta_Y = \tan^{-1}\frac{+B}{G} = -\theta_Z$</td></tr>
<tr><td colspan="2">IA</td><td colspan="2">IB</td><td colspan="2">IIA</td><td colspan="2">IIB</td></tr>
<tr><td colspan="2">15. $Q = -I^2X$<br>16. $= -E^2B$<br>17. $= +EI \sin\theta_Y$</td><td colspan="2">$Q = +I^2X$<br>$= +E^2B$<br>$= +EI \sin\theta_Z$</td><td colspan="2">$Q = -I^2X$<br>$= +E^2B$<br>$= +EI \sin\theta_Y$</td><td colspan="2">$Q = +I^2X$<br>$= -E^2B$<br>$= +EI \sin\theta_Z$</td></tr>
<tr><td>IAa</td><td>IAb</td><td>IBa</td><td>IBb</td><td>IIAa</td><td>IIAb</td><td>IIBa</td><td>IIBb</td></tr>
<tr><td>18. $V = P + jQ$</td><td>$V = P - jQ$</td><td>$V = P + jQ$</td><td>$V = P - jQ$</td><td>$V = P - jQ$</td><td>$V = P - jQ$</td><td>$V = P + jQ$</td><td>$V = P - jQ$</td></tr>
<tr><td colspan="8">*For a circuit in which inductance predominates Q will be drawn*</td></tr>
<tr><td>19. down</td><td>up</td><td>up</td><td>down</td><td>down</td><td>up</td><td>up</td><td>down</td></tr>
</table>

*For either of these conventions, the reactive volt-amperes $Q$ may conceivably be defined as either + or −, thus giving 4 alternatives, and (if a further violation of principle 2 is invoked) each of these 4 alternatives gives rise to 2 ways of drawing the power triangle; i. e., as $V = P + jQ$ or as $V = P - jQ$. The resulting 8 procedures are here shown in tabular form.

one which does not involve at least one violation of principle 2 or 4 in addition to the unavoidable violation at step 12 or 13 which occurs in all procedures. Alternatives **IIA** and **IIB** both suffer from the inconvenient change in form (though not in substance) according as $Q$ is defined from $X$ or from $B$.

The drawing of the power vector parallel to the current vector (down in the inductive case) is attained in **IAa, IBb, IIAa** and **IIAb.**

In addition to the formal principles listed above consideration should also be given to the following facts:

20. The almost universal use of constant voltage systems for the transmission and utilization of electric power makes the calculation of circuits by using their admittance, conductance, and susceptance the most logical and direct.

21. Habits of thought arising by the historical accident that series circuits were first studied theoretically make the average engineer more familiar with the quantities impedance, resistance, and reactance.

22. The use of reactive power as equivalent to $2\omega(W_m - W_e)$ where $W_m$ and $W_e$ are the magnetic and electrostatic energies, has already come into considerable use in the literature.

## Discussion

For discussion of this paper see page 779.

# Reactive and Fictitious Power

BY V. G. SMITH*
Associate, A.I.E.E.

***Synopsis.**—In this paper the single-phase and polyphase definitions of reactive power are considered. The single-phase definition is unsatisfactory when the current and voltage wave forms are complex. The polyphase definition is the better but requires the independent recognition of the effects of distortion and, in the case of four or more wires, mesh distribution. The geometric difference between the apparent power and the power may be called the fictitious power to distinguish it from the reactive power which is only part of the fictitious power.*

THE conception of reactive power originated in the single-phase sinusoidal problem. In attempting to extend the idea to complex waves and multiple phases, certain difficulties arise which are well worth investigation.

## SINGLE-PHASE

In the A.I.E.E. rules there are 2 definitions of reactive power, $\pm\sqrt{E^2I^2 - P^2}$ for single-phase and $\Sigma E_nI_n \sin \theta_n$ for polyphase circuits, the summation extending over all harmonics and all phases. Applied to single-phase cases they cannot be reconciled except for sine waves or a load of pure resistance or its equivalent.

It may be shown[1] (for references see list at end of paper) that

$$E^2I^2 - P^2 = \{\Sigma E_nI_n \sin \theta_n\}^2 + [\Sigma\{E^2{}_mI^2{}_n - 2E_mE_nI_mI_n \cos(\theta_m - \theta_n) + E^2{}_nI^2{}_m\}] = P^2{}_r + P^2{}_d \qquad (1)$$

where $P_r$ is the reactive power by the polyphase definition and $P_d$ is the square root of the fourth term. This fourth term will vanish if the circuit presents the same impedance to all harmonics, i. e., if

$$\theta_m = \theta_n \text{ and } E_m/I_m = E_n/I_n \qquad (2)$$

This quantity is due therefore to the distorting effect of the circuit and $P_d$ may be called the "distortion" power. (In the Roumanian Questionnaire[2] it is called the "deforming" power but the word "distortion" is already well established in communication literature.) The relations between these quantities are shown in Fig. 1.

## ALGEBRAIC SIGNS

The idea of an algebraic sign is natural for sine waves and it is best to define leading reactive power as positive. Now the quantity $\pm\sqrt{E^2I^2 - P^2}$ may exist when there is no lead or lag but merely distortion.[3] In such cases which sign shall be used? On the other hand the quantity $\Sigma E_nI_n \sin \theta_n$ has a definite algebraic sign depending upon the sinusoidal definition. Budeanu has called $P_f = \sqrt{E^2I^2 - P^2}$ the fictitious power. Apparently $P_d$ and $P_f$ may be taken as positive, no significance being attached to a negative sign.

The case of a sinusoidal voltage applied to a cyclically variable resistance is often quoted to show that $\sqrt{E^2I^2 - P^2}$ may exist when there is no electromagnetic energy storage, but it should be pointed out that $P_r = \Sigma E_nI_n \sin \theta_n$ may also exist under the same conditions if the resistance cycle is unsymmetrical with respect to the voltage maximum. This would occur where there was heat storage. The reactive power $P_r$ therefore is, in the most general case, an abstract mathematical quantity. [1] (When an opinion is expressed concerning one of the questions in the Roumanian Questionnaire the number of the question is given in square brackets.)

In spite of the fact that distortion and electromagnetic energy storage are inextricably mixed in the most general case, $P_r = \Sigma E_nI_n \sin \theta_n$ is the best definition of reactive power yet proposed. It forms a symmetrical pair with $P = \Sigma E_nI_n \cos \theta_n$, reduces correctly to the sinusoidal form in all cases, and determines the algebraic sign. Thus the reactive power of a neon sign with a resistor ballast is zero but the distortion power is not. As the phenomenon is really distortion it is surely better so to describe it. [9]

## POLYPHASE CIRCUITS

The reactive power $P_r = \Sigma E_nI_n \sin \theta_n$, has an immediate meaning in a polyphase circuit. The order of summation, over phases or harmonics, and the point to which the potential differences are measured, are immaterial. However, it does not give complete information about the system.

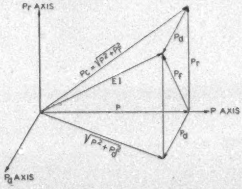

FIG. 1—VECTOR RELATION BETWEEN POWER, REACTIVE POWER, FICTITIOUS POWER, DISTORTION POWER, AND COMBINED POWER IN A SINGLE-PHASE CIRCUIT

---

*Assistant Professor of Electrical Engineering, University of Toronto, Ontario, Can.

*Presented at the North Eastern District Meeting of the A.I.E.E., Schenectady, N. Y., May 10–12, 1933.*

Fortescue[4] has suggested a definition based on symmetrical components but it is limited to sine waves and is too special to serve as a general definition. The fictitious power in polyphase circuits may be defined as $P_f = \sqrt{P^2_{ap} - P^2}$, where $P_{ap}$ is the apparent power. The only satisfactory definition of the apparent power is that of Lyon[5] and Liénard.[3] It is the maximum power obtainable when the phases and wave forms of the currents and voltages are varied in every possible manner consistent with Kirchhoff's laws, the effective values remaining constant.

### POLYPHASE CIRCUITS WITH SINE WAVES

The reactive power $P_r = \Sigma E_n I_n \sin \theta_n$, is the natural definition with sine waves and is the one always used. It makes $P_r$ the algebraic sum of the reactive powers of the load elements. Fictitious power can occur even with sine waves if the circuit is of 4 or more wires. This includes the case of the 3-phase 4-wire circuit.

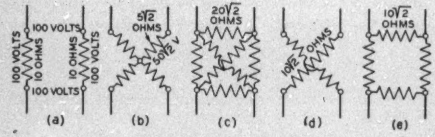

FIG. 2—AN EXAMPLE OF FICTITIOUS POWER IN A TWO-PHASE FOUR-WIRE MESH CIRCUIT

It is shown in Appendix I that the stationary values of the power occur when each line current is in phase with or in opposition to the voltage from the corresponding line to some common point. Among these stationary values is the greatest power, $P_{ap}$.

The simplest type of load to meet these requirements is a star of positive and negative resistances with the neutral point as the common point in question. If it is possible to secure the given root mean square line currents by means of a star of all positive resistances, that star is unique and takes the greatest possible power, $P_{ap}$. Sometimes, however, it is necessary to introduce 1 or 2 negative resistances.

A mesh of pure resistances will not in general be such as to cause the line currents to be in phase with or opposed to the voltages to some common point. Consequently the power is less than $P_{ap}$ and fictitious power,

$$P_f = \sqrt{P_{ap}{}^2 - P^2} \tag{3}$$

exists. It is not due to energy storage or distortion but to the distribution of the elements of the mesh and may be called the "fictitious mesh power." Meshes which are equivalent to some pure resistance star will not show fictitious power. Other meshes may show fictitious power on one voltage system and not on another.

A simple example in a 2-phase 4-wire circuit is shown in Fig. 2. Let (*a*) be the actual load and (*b*) the star which takes the same line currents. Both take 10 amp per line but in (*a*) the power is only 2 kw while in (*b*) it is $2\sqrt{2}$ kw. The fictitious mesh power of (*a*) is $\sqrt{(2\sqrt{2})^2 - 2^2} = 2$ kw. Circuit (*c*) is the mesh equivalent to (*b*) while (*d*) and (*e*) take the same power as (*b*) on the balanced voltages but would not in general take the same power.

In the case of 3 wires the mesh is a delta which may be reduced to a wye. A pure resistance delta can show no fictitious mesh power. In fact, it may be shown that the power is a maximum when the total reactive power is zero whether the load is a pure resistance or not and that the 3 line currents are then in phase with the voltages to a common point. The maximum power $P_{ap}$ is $\sqrt{P^2 + P_r^2}$, for 3 wires, sine waves, and there is no such thing as fictitious mesh power in this case.

### POLYPHASE CIRCUITS WITH COMPLEX WAVES

It is shown in Appendix II that the resistance star is the type of load which absorbs the greatest power when the wave forms are complex. In some cases 1 or 2 negative resistances may be necessary. All that has been said concerning meshes and fictitious mesh power in the sinusoidal case applies equally well here. The 3-wire case is again special and will not show fictitious mesh power. When the mesh is not formed of pure resistances the distortion and mesh parts of the fictitious power are inextricably combined.

### MEASUREMENTS

The measurement of $\sqrt{E^2 I^2 - P^2}$ directly would be very difficult but each quantity in it may be measured with considerable accuracy. The measurement of $\Sigma E_n I_n \sin \theta_n$ is theoretically possible by means of a series of perfect filters, provided the frequency were absolutely constant. In practice, the voltages are usually nearly enough sinusoidal and balanced that the method of applying a quadrature voltage to a wattmeter is sufficiently accurate. If the voltages are sinusoidal and balanced the wave forms and unbalance of the currents do not matter provided proper methods are used. No direct method of measuring the apparent power or the fictitious power in a polyphase network is known. The currents, voltages, and power may be measured and in some cases the apparent and fictitious powers calculated from them.

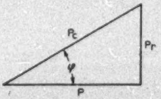

FIG. 3—RIGHT-ANGLED TRIANGLE CONNECTING $P$ $P_r$ AND $P_c$. IN THE PROPOSED DEFINITION $P_c$ WOULD NOT EQUAL $VI$ AND THE ANGLE $\varphi$ WOULD HAVE NO MEANING APART FROM THE TRIANGLE

## CONCLUSIONS AND SUGGESTIONS

The existing definition of reactive power in a single-phase circuit, $\pm\sqrt{E^2I^2 - P^2}$, leads to an unsatisfactory situation when the waves are complex. Any attempt to extend it in the form $\pm\sqrt{P^2_{ap} - P^2}$ to polyphase circuits leads to the conclusion that a pure resistance mesh must be considered to cause reactive power. This rules out the wattmeter method of measurement and provides no other in its place, a procedure to which metermen would strenuously object. Of course this is due to the Lyon-Liénard definition of apparent power, but what other definition is possible?

In spite of the difficulties of measurement the definition $P_r = \Sigma E_n I_n \sin\theta_n$ is much the better even for single-phase circuits. Distortion power and fictitious mesh power increase the losses the same as reactive power. If the polyphase definition is to be used it is necessary to recognize the effects of distortion and, in the 4-wire circuit, mesh distribution. [8.]

It is perhaps well to point out that the adoption of this definition will not increase the difficulties of measurement. Distortion and fictitious mesh power are there now but are neglected by the measuring apparatus; the new definitions merely would call attention to their existence.

The following definitions are suggested:

1. Reactive power $P_r = \Sigma E_n I_n \sin\theta_n$ under all conditions. This is the present polyphase definition. [14.]
2. The apparent power $P_{ap}$ is the maximum possible power with the given effective voltages and currents. In the case of a single phase this is $EI$. [10.]
3. The fictitious power is $P_f = \sqrt{P^2_{ap} - P^2}$. [15.]
4. The combined power is $P_e = \sqrt{P^2 + P^2_r}$.
5. The power factor is $P/\sqrt{P^2 + P^2_r} = P/P_e$.
6. The reactive factor is $P_r/P$. This term has another meaning at present but is not much used.[6] [14.]
7. The distortion power in a single-phase circuit is
$P_d = \sqrt{P^2_f - P^2} =$
$\sqrt{\Sigma\{E^2_m I^2_n - 2E_m E_n I_m I_n \cos(\theta_m - \theta_n) + E^2_n I^2_m\}}$.
8. The distortion factor in a single-phase circuit is $P_d/P$.

It does not seem necessary to define fictitious mesh power as it is included in definition 3 of fictitious power.

## ROUMANIAN QUESTIONNAIRE

Comments on some of the questions of the Roumanian Questionnaire[2] follow.

[2]. The form $VI\sin\varphi$ would have to be dropped entirely. A right-angled triangle would still exist connecting $P$, $P_r$ and $P_e$, as in Fig. 3 but the angle $\varphi$ would have no meaning apart from the triangle. The power factor would be $\cos\varphi$ and the reactive factor (new) $\tan\varphi$. [11]. The forms $P = P_e\cos\varphi$ and $P_r = P_e\sin\varphi$ exist but $P_e$ is not $VI$.

[8]. It seems clear that the general case is too complicated to be described completely by the single term "reactive power." Distortion and fictitious mesh power are very difficult to determine and it would be advisable to separate reactive power from them for that reason. In addition there is the advantage of retaining an algebraic sign. [12, 13]. By adopting an algebraic definition of reactive power all need for such terms as "inductive power" and "capacitance power" disappear. The former is negative and the latter positive reactive power.

# Appendix I

### SINE WAVES

The following discussion is limited to 4 wires though it could just as well apply to $n$ wires. The vector notation $\boldsymbol{A}\cdot\boldsymbol{B} = AB\cos\theta$, where $A$ and $B$ are the tensors of $\boldsymbol{A}$ and $\boldsymbol{B}$ and $\theta$ the angle between them, is used.

The total power in a 4-wire circuit may be measured by regarding it as 4 single phases with voltages to any common point. That is

$$P = \sum \boldsymbol{E}_{ro}\cdot\boldsymbol{I}_r = \sum \boldsymbol{E}_{rp}\cdot\boldsymbol{I}_r \tag{4}$$

where $o$ and $p$ are any points, $p$ being thought of as a variable.

Given the effective voltages and line currents, the maximum possible power is required. The voltage system is completely fixed. The variables are the phases of the currents relative to the voltages and subject to the condition $\sum\boldsymbol{I} = 0$

When the currents vary

$$\delta P = \sum \boldsymbol{E}_{rp}\cdot\delta\boldsymbol{I}_r \tag{5}$$

To make the power a maximum this must be zero for all consistent sets of current increments. As in Fig. 4 it is possible to vary any 3 currents and leave the other fixed. Also, since the current magnitudes are given the increments must be at right angles to the currents, i. e.

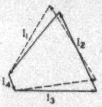

FIG. 4—VARIATION OF LINE CURRENTS

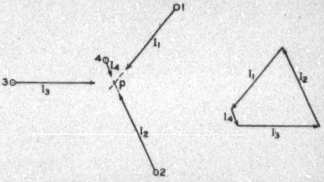

FIG. 5—TOPOGRAPHICAL DIAGRAM

$$\boldsymbol{I}_r\cdot\delta\boldsymbol{I}_r = 0 \tag{6}$$

Now suppose all the voltages are plotted topographically as in Fig. 5, and that all the currents are plotted from their respective wire positions as shown. Let the currents in the lines 1, 2, and $r$ vary ($r$ = 3 or 4), the other being constant, then

$$\delta P = \boldsymbol{E}_{1p}\cdot\delta\boldsymbol{I}_1 + \boldsymbol{E}_{2p}\cdot\delta\boldsymbol{I}_2 + \boldsymbol{E}_{rp}\cdot\delta\boldsymbol{I}_r \tag{7}$$

Now let the point $p$ be chosen at the intersection of the vectors $\boldsymbol{I}_1$ and $\boldsymbol{I}_2$ produced. Then $\delta I_1$ is at right angles to $\boldsymbol{E}_{1p}$ and hence

$$\boldsymbol{E}_{1p}\ \delta\boldsymbol{I}_1 = 0 \tag{8}$$

Similarly

$$\boldsymbol{E}_{2_p} \cdot \delta \boldsymbol{I}_2 = 0 \tag{9}$$

Therefore to make $\delta P = 0$ it follows that

$$\boldsymbol{E}_{rp} \cdot \delta \boldsymbol{I}_r = 0 \tag{10}$$

or since $\boldsymbol{I}_r \cdot \delta \boldsymbol{I}_r = 0$, the vector $\boldsymbol{I}_r$ also points directly toward or away from the point $p$.

For a stationary value of the power therefore all currents must be in phase with or opposed to the voltages to some common point. The point must be chosen so that $\sum \boldsymbol{I} = 0$.

## Appendix II

### Complex Waves

The problem is to determine the conditions for maximum power when the waves are complex, given only the effective currents and voltages. For the present suppose that not only are the effective voltages given but also their harmonic components so that the voltage system is completely specified. The line currents may be resolved into harmonic systems quite arbitrarily provided that the vector sum of each harmonic in the 4 lines is zero and that the effective current in each line is as given.

Now suppose that by means of perfect filters each harmonic current system has its own load. Let each of those loads be the star load which gives the greatest power for that harmonic. For any chosen current system this method of loading gives the greatest possible power. It remains to find which of the arbitrary current systems is the best.

Let there be 4 wires and let $\boldsymbol{I}_{ms}$ be the $s^{th}$ harmonic of current in the $m^{th}$ line and let $\boldsymbol{E}_{ms}$ be the $s^{th}$ harmonic of voltage from the $m^{th}$ line to the neutral of the $s^{th}$ harmonic load, then

$$P = \sum_{s=1}^{\infty} \sum_{m=1}^{4} \boldsymbol{E}_{ms} \cdot \delta \boldsymbol{I}_{ms} \tag{11}$$

Also

$$\sum_{m=1}^{4} \boldsymbol{I}_{ms} = 0 \tag{12}$$

by Kirchhoff's first law, and

$$\sum_{s=1}^{\infty} I_{ms}^2 = I_m^2 \tag{13}$$

where $I_m$ is the effective current in the $m^{th}$ line.

When the current system is varied the star loads vary and hence also the voltages to the neutrals. Then,

$$\delta P = \sum_{s=1}^{\infty} \sum_{m=1}^{4} (\boldsymbol{E}_{ms} \cdot \delta \boldsymbol{I}_{ms} + \delta \boldsymbol{E}_{ms} \cdot \boldsymbol{I}_{ms}) \tag{14}$$

$$= \sum_{s=1}^{\infty} (\sum_{m=1}^{4} \boldsymbol{E}_{ms} \enspace \delta \boldsymbol{I}_{ms} + \delta \boldsymbol{E}_{ms} \cdot \sum_{m=1}^{4} \boldsymbol{I}_{ms}) \tag{15}$$

since $\delta \boldsymbol{E}_{ms}$ is common to all 4 lines. By eq 12 the second term of eq 15 is zero, hence

$$\delta P = \sum_{s=1}^{\infty} \sum_{m=1}^{4} \boldsymbol{E}_{ms} \cdot \delta \boldsymbol{I}_{ms} = \sum_{s=1}^{\infty} \sum_{m=1}^{4} r_{ms} \, \boldsymbol{I}_{ms} \cdot \delta \boldsymbol{I}_{ms} \tag{16}$$

$$= \frac{1}{2} \sum_{s=1}^{\infty} \sum_{m=1}^{4} r_{ms} \, \delta \boldsymbol{I}_{ms}^2 \tag{17}$$

where $r_{ms}$ is the resistance of that element of the $s^{th}$ harmonic load which is connected to the $m^{th}$ wire.

Differentiating eq 13

$$\sum_{s=1}^{\infty} \delta I_{ms}^2 = 0 \tag{18}$$

Now it is possible to change the amplitude of any 2 harmonics in the same wire leaving all others constant. The phases of the corresponding harmonics in other wires must be changed but their amplitudes need not. Let only the $s^{th}$ and $t^{th}$ harmonics of current in the $m^{th}$ wire be given increments, then

$$2\delta P = 0 = r_{ms} \, \delta I_{ms}^2 + r_{mt} \, \delta I_{mt}^2 \tag{19}$$

$$0 = \delta I_{ms}^2 + \delta I_{mt}^2 \tag{20}$$

since if $P$ is to be a maximum $\delta P$ must be zero for all possible variations.

From these 2 equations it is seen that

$$r_{ms} = r_{mt} \tag{21}$$

or that all the harmonic loads are equal for a maximum power. The filters are therefore unnecessary and a single star load absorbs the greatest power.

It may be shown that the power to such a star load depends only upon the resistances and the effective voltages and hence the assumption of given voltage wave forms was immaterial. Also given the effective voltages and line currents the star resistances are independent of the actual voltage wave forms.

# Operating Aspects of Reactive Power

BY J. ALLEN JOHNSON*
Fellow, A.I.E.E.

***Synopsis.***—*This paper is written to present the point of view of the practical operating engineer to whom "reactive power" is something that he has to generate and deliver to his customers much as he does ordinary or real power. It happens that this kind of reactive power is the kind which causes the current to lag behind the voltage when it happens to be flowing in the same direction in the circuit as the "active" power. However, when it happens to be flowing in the direction opposite to that of the active power (which, in a transmission system is just about as likely to happen), it makes the total current in the circuit appear to lead the voltage and deceives the technician who observes this phenomenon into thinking that a different kind of reactive power (viz., leading reactive power) is flowing in the same direction as the active power.*

*The paper presents an interpretation of such observations in terms of the one kind of reactive power with which the practical operation and control of power systems has to deal and points out the parallelism between active and reactive power in their operating aspects.*

*It also presents an unorthodox metering technique for keeping track of the flow of reactive power in a complicated power transmission network which greatly clarifies and simplifies the problem of dispatching reactive power in such a system; such dispatching being necessary to obtain maximum transmission system capacity and efficiency as well as for system voltage control.*

*No pretense is made of presenting any newly discovered truths. Rather the attempt is to present a new way of looking at old truths. The point of view is believed to be somewhat novel and may do mild violence to some orthodox conventions. This violence, however, is believed to be justified by the resulting clarification in the operating aspects of reactive power.*

---

THE subject of the symposium of which this paper is a part is "reactive power." This term is somewhat unfamiliar to many engineers, and some might even strongly deny the existence of reactive "power." The conception of reactive current as "wattless" is so deeply ingrained that the term "reactive power" will doubtless meet with reluctant acceptance. In one sense this conception of "wattlessness" is true, but in another, and the author believes, equally valid sense, it seems to him not to be true. The author therefore proposes to accept the title at its face value, and as an engineer in the operating field, present a point of view in which reactive power is conceived of as a kind of power different and distinct from power in its ordinary meaning (which hereinafter will be called "active" power) but with which the operator nevertheless has to deal in much the same manner.

### TWO VIEWS OF REACTIVE POWER

There are two points of view from which the subject of reactive power may be regarded. The first of these may be called the academic, mathematical, or technical point of view, and the second the practical, engineering, or operating point of view. Let us first clearly distinguish between these two points of view which we will call briefly the "academic" and the "practical."

### CHARACTERISTICS OF ACADEMIC VIEW

The academic point of view results from consideration of what is going on at a certain point in a circuit. Instruments are inserted and measurements made of current, potential, and power. From these it is often found that the measured watts are less than the product of the measured amperes and the measured volts by a certain factor, which we call the "power factor." From these relationships and familiar known laws, we can determine the in-phase and quadrature components of the flow (and their phase relationship) which in this view we think of as inseparable and more or less imaginary components of the "total kilovolt-amperes" in the circuit. While this technique does inform us fairly well as to what is occurring at the point of measurement, it does not lend itself at all well to the visualization of what is happening in the system as a whole nor to a practical technique of system control. It does not give us the picture of two independent things going on in the circuit at the same time.

In representing these quantities and relationships on paper the technician uses a device which he calls a "vector diagram." In such diagrams, counterclockwise vector rotation is usually considered standard, and right hand and upward vectors, positive. The "academic" viewpoint seems to have its origin in these conventions, as does also the question as to the "sign" of reactive power.

### CHARACTERISTICS OF PRACTICAL VIEW

The "practical" point of view results from a consideration of what is going on, not at one point in a circuit but throughout the entire electrical power system. The operating engineer is faced with the problem of controlling the operation of his system and hence is interested in tracing the two kinds of power flow found at any one point back, on the one hand, to their sources and forward, on the other hand, to their destinations, in order to discover how he can control their sources in and courses through the system. What does he find?

He finds that the active power (neglecting losses for the moment) originates in a prime mover, passes thence through a mechanical connection of some sort into a "generator" where it is converted into electrical power. After traversing the system this power arrives (let us say) at induction motors where it is converted back to mechanical power and passes on to the driven machines. Or it may be converted directly into heat and leave the electrical system in

---

*Presented at the North Eastern District Meeting of the A.I.E.E., Schenectady, N. Y., May 10–12, 1933.*

that form. In any case it flows, like a stream, into the electrical system at one end and out at the other.

He finds that the demand for reactive power originates for the most part in the excitation requirements of induction motors and other devices using iron magnetic circuits which draw their excitation, in the form of lagging reactive current, from the same circuits through which the active power is flowing. Following this reactive power back through the system he finds that it has its origin in the field circuits of the generators. He knows this must be so because he finds he can control the amount of reactive power supplied by any particular generator by varying its field current. This reactive power therefore apparently originates within the electromagnetic system and never leaves it, but reacts back and forth between the generators and the motors. Hence its name "reactive power" and its logical symbol *rkw* used hereinafter. [EDITOR'S NOTE: The author's symbol *rkw* (and the corresponding term *reactive kilowatt*) is used advisedly in this paper, rather than the standard editorial style *rkva*, or the symbol *kvar* adopted by the International Electrotechnical Commission, July 9, 1930.]

He further finds that the flow of the active power through his system produces comparatively little drop in potential, whereas the flow of reactive power is much more serious in this respect; also that if the reactive power is generated in the same generators through which active power is supplied, and flows through the same circuits, it requires increased current capacity of generators, transformers, and lines, increases $I^2R$ losses in all current carrying parts of the system, and limits the active power capacity of the transmission circuits. He finds, however, that active and reactive power do not add together in these circuits algebraically but geometrically in quadrature.

Since reactive power originates in generators and not in prime movers, the generation of reactive power is not subject to the same limitations as to geographical location as is that of active power, but can be generated anywhere desired. Therefore, in order to minimize its undesirable effects on the major parts of the system, reactive power generators (commonly called synchronous condensers) are frequently installed at receiving or distributing substations near the load where the reactive power is required. In many cases generators used to supply active power during one set of conditions may be used to supply reactive power during other conditions.

Since the active and reactive power do not add algebraically but combine in quadrature relation it is obviously more economical, other things being equal, to generate both in the same machine. Where both can be generated near the point of use, this usually proves to be the case, but where the active power must be transmitted long distances, it often proves more economical to generate the reactive power in separate machines near the load, even at the expense of increased total machine capacity. This practice also provides a means of regulating voltage at the receiving end of the lines.

As the two kinds of power—active and reactive—flow through the system, losses of both kinds occur due to the resistance, reactance, and capacitance of the circuits. The losses of active power, due to the resistance, are all positive with respect to the active power transmitted and result in less active power being received at the load than left the prime movers. The losses of reactive power, however, with respect to the reactive power transmitted, may be either positive or negative or both, positive losses being due to reactance and negative losses to condensance. It follows that the amount of reactive power delivered to the load may be either more or less than the amount generated.

Let us now inquire what are the conditions and problems confronting the power system operator in controlling his system. Briefly they are as follows:

1. A demand for active power by the customers of the system, and over which he has little or no control.
2. Sources of supply of active power in the form of steam and hydroelectric generating units, perhaps widely scattered, and over which he has control.
3. A demand for reactive power, principally for exciting the motors of the customers, and over which he has little or no control.
4. Various possible sources of reactive power including all of the synchronous generators, condensers, and motors on the system, and over most of which he has control.
5. The demands must be supplied from the various available sources in the most economical manner possible at all times.
6. Voltage must be maintained within certain limits at all stations on the system.

Various other conditions must usually be met but these are the ones with which reactive power is mostly concerned.

In order to operate his system efficiently, and properly control its voltage, the power system operator or load dispatcher must be able to control not only the sources, magnitudes, and directions of the active power flow but also the sources, magnitudes, and directions of the reactive power flow. The magnitude and direction of the active power flow are in practice controlled by adjusting the input to the proper prime movers. The magnitude and direction of the reactive power flow are similarly controlled by adjusting the field currents of the proper generators. To increase the amount of active power supplied by a prime mover the operator increases its power input by increasing its gate or throttle opening. Similarly, to increase the reactive power supplied by a generator or synchronous condenser operating in parallel with other synchronous machines, he increases its field excitation by adjusting its exciter or field rheostat. The two processes are analogous and parallel, but independent of each other.

## MEASURING INSTRUMENTS

The above are the processes by which the independent control of active and reactive power are effected. To know how to apply these controls, however, it is necessary to measure the magnitudes of the active and reactive power and for this purpose suitable instruments are necessary. The old technique of using wattmeters and power-factor meters was based upon the "academic" viewpoint, in which the total flow in the circuit was treated as a unit. The "practical" viewpoint calls for separate instruments to read the active power and the reactive power. Standard wattmeters will serve both purposes when suitably connected to the circuit. In circuits in which active power can flow in only one direction, left-hand zero instruments can be used for the active power. Where active power may flow in either direction, however, center zero instruments are commonly used. Since reactive power can flow in either direction in practically all circuits, center zero instruments are desirable to measure reactive power in practically all cases.

In the "academic" view, the sense or direction of the reactive power is defined by reference to that of the active power by saying that it "leads" or "lags" according as the current vector leads or lags the potential vector. In a circuit in which active power can flow in only one direction, such as a generator or a radial distribution circuit, this convention leads to little or no confusion. This, however, is not the case in a complicated power network, with widely distributed sources of active and reactive power, and with widely distributed loads, wherein almost any circuit may be called upon to transmit active and reactive power independently in either direction. In such a system, the sources and destinations of reactive power are visualized in the mind of the operator just as definitely as are the sources and destinations of the active power, and it consequently becomes much more natural and logical for him to relate the sense or direction of flow of the reactive power to the circuit in which it is flowing just as he does in the case of the active power rather than to relate it vectorially to the flow of the active power as in the conventional "academic" point of view. Thus, in this "practical" point of view the flows of active and of reactive power become entirely divorced from each other, the direction of flow of each being independently related to the circuit instead of one to the other.

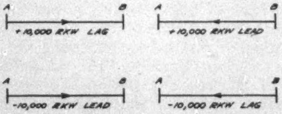

FIG. 1—FOUR WAYS OF DEFINING THE FLOW OF REACTIVE POWER IN A CIRCUIT

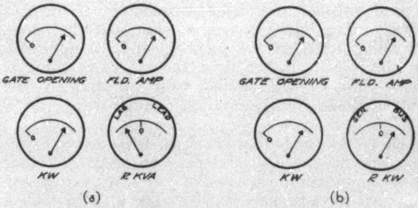
The conventional system of marking power factor and reactive power meters in terms of "lead" and "lag" thus, in a large power system, introduces difficulties in properly reading and interpreting the readings of these instruments. In a two-way circuit, owing to the reversible flow of active power, the interpretation of the readings is very confusing as it is impossible to tell, from the readings of the instruments marked in this way, the direction of the reactive power flow unless one knows how the instruments are connected.

Accepting the "practical" convention that reactive power flow is to be defined independently of the active power flow and in relation to the circuits in the same way as the active power flow is defined, it becomes necessary to adopt a convention as to the kind of reactive power that we will talk about. It immediately appears that with this method of treatment it is no longer necessary to discuss both leading and lagging reactive power, since leading reactive power flowing in one direction in the circuit is identical with lagging reactive power flowing in the other direction. Since, as above noted, in a normal electric power system the demand for lagging reactive power predominates over that for leading reactive power and furthermore since the demand for lagging reactive power has its origin in machines with the characteristics of which the operators are familiar and its source is in other machines with the characteristics of which the operators are also familiar, and over which they have control; whereas a demand for leading reactive power is of much rarer occurrence and less familiar to operating men, it follows that *the requirements of operation will be best served if all reactive power flow is treated as lagging reactive power flowing in a certain direction in the circuit.*



(a) (b)

FIG. 2—ACADEMIC (a) AND PRACTICAL (b) METHODS OF METERING THE OUTPUT OF A GENERATING UNIT

In the academic (conventional) method the field ammeter and reactive power meter pointers move in opposite directions when adjustments of field current are made. In the practical method this inconsistency is eliminated by reversing the connection of the "reactive kilowatt" meter

This is not difficult to do and when it is done consistently it results in the removal of a number of difficulties in handling reactive power flow on a power system. If, in the circuit *AB* of Fig. 1 there are 10,000 *rkw* lagging flowing from *A* to *B*, we can represent the same condition by saying there are −10,000 *rkw* lagging flowing from *B* to *A*, or there are 10,000 *rkw* leading flowing from *B* to *A*, or there are −10,000 *rkw* leading flowing from *A* to *B*. So, a leading *reactive kilowatt* in a circuit can always be represented by a lagging *reactive kilowatt* in the opposite direction; and vice versa, a lagging *reactive* *kilowatt* can always be represented by a leading *reactive kilowatt* in the opposite direction. Therefore, if we should decide to deal with only one kind of reactive power and further decide that that one kind shall be "lagging," any *reactive kilowatt* which formerly was called "leading" will now be called "lagging," with the direction of flow reversed. In Fig. 1 are shown the four different ways of representing exactly the same condition.

## CONVENTIONS FOR OPERATION

With the foregoing in mind, and with the aim to obtain a system which is simple and easy to understand and remember, the following conventions might be adopted by an operating power system.

1. Reactive power will always be represented in terms of lagging reactive power and will be designated by the symbol *rkw*.
2. On station log sheets and similar records all readings will be given as a flow between two points. The names of these two points will be written down in their proper order and connected by a dash or hyphen, such as: "Gen. No. 1–12-kv Bus" or "Lockport-Mortimer." (In this system, transmission circuits are designated by the names of the terminal bus points.) The magnitudes of the kilowatt and *reactive kilowatt* readings will then be recorded and an arrow written just before (or after) each quantity. These arrows will point in the direction of flow as referred to the corresponding points. For example, since "Lockport" is written to the left of "Mortimer" on the log sheet, if power flow is actually from Mortimer to Lockport, the arrow preceding the kilowatt figure will point to the left on the log sheet. Similarly, if reactive power flow is actually from Lockport to Mortimer, the arrow preceding the *reactive kilowatt* figure will point to the right on the log sheet.
3. In marking values of kilowatt and *reactive kilowatt* flow on diagrams, as a matter of convenience, only one arrow need be used to represent the direction of simultaneous flow of kilowatts and *reactive kilowatts* in the same circuit. This arrow may point in the actual direction of kilowatt flow. The kilowatt and *reactive kilowatt* quantities will then be marked beside the arrow. The kilowatt flow will be represented by a positive (+) quantity. The *reactive kilowatts* will be represented by a positive (+) quantity if its flow is actually in the same direction as the kilowatt flow, and by a negative (−) quantity if its flow is actually in the direction opposite to the kilowatt flow.

## APPLICATION OF THE CONVENTIONS—APPARATUS

If a generator, in parallel with other synchronous machines, is delivering active power only, an increase in field current will cause it to generate (lagging) reactive power, while a decrease in field current will cause it to consume (lagging) reactive power.

For the station operator, it may be interesting and helpful to note here that, having standardized on lagging reactive power, and adopted corresponding instrument connections and labelling (see Fig. 2) increasing the gate opening and increasing the field current of a generating unit operating in parallel with other synchronous machines have similar effects, in that the former causes an increase in kilowatt output (kilowatt meter pointer moves to the right) and the latter causes an increase in *reactive kilowatt* output (*reactive kilowatt* meter pointer moves to the right). Furthermore, it will be noted that the field ammeter pointer and *reactive kilowatt* meter pointer will always move in the same direction, that is, when one is moving from left to right, the other will also be moving from left to right, and vice versa. This consistency, uniformity, and simplicity are in striking contrast to the illogical and confusing inconsistency where the present "academic" standard marking and conventions are used, where lagging reactive output deflects the instrument pointer in the opposite direction from that of the field ammeter.

A synchronous condenser being a reactive power generator, a similar explanation applies. If the condenser is running at unity power factor (simply drawing kilowatts to supply internal losses), an increase in field current will cause it to deliver (lagging) reactive power to the circuit, while a decrease in field current will cause it to draw (lagging) reactive power from the circuit.

Unloaded transmission circuits have generally been said to be drawing leading reactive kilovolt-amperes but, according to the new conventions, we shall say they deliver (lagging) reactive power (*rkw*).

An induction motor draws (or consumes) (lagging) reactive power (*rkw*) from the circuit.

A static condenser delivers (lagging) reactive power (*rkw*) to the circuit.

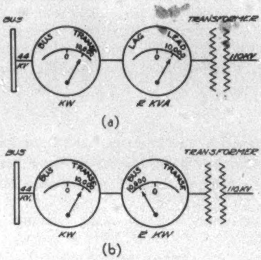


FIG. 3—ACADEMIC (a) AND PRACTICAL (b) METHODS OF METERING REVERSIBLE CIRCUITS

Interpretation of readings under academic method requires knowledge as to how reactive kilovolt-ampere meter is connected with reference to kilowatt meter, i. e., whether "lag" and "lead" apply to power flow from bus to transformer or from transformer to bus. With the practical method this knowledge is not needed, all the information required being provided by the labelling of the meter scales

## REACTIVE POWER (RKVA) (*RKW*) METER

In general practice, reactive kilovolt-amperes have been designated as being either "leading reactive kilovolt-amperes" or "lagging reactive kilovolt-amperes." Each of these, as above stated, can flow in either of two directions. On the other hand, active power (or simply power) has always been designated as just plain "kilowatts." In other words, in order to qualify a kilowatt meter reading completely, it has been necessary to state only magnitude and direction of flow, whereas, in the case of a reactive kilovolt-ampere meter reading, it has been necessary to state magnitude, kind (leading or lagging), and direction of flow.

Since, in this standardization, all reactive power will be represented in terms of lagging reactive power, both active power and reactive power values will be completely qualified by magnitude and direction of flow. "Reactive kilovolt-ampere" meters will now become "lagging *reactive kilowatt*" meters, and their readings will always be in lagging *reactive kilowatts*.

### *RKW* METER WITH TWO-WAY KW METER

In metering a piece of apparatus whose kilowatt flow is always in the same direction, no trouble should be experienced. Now, let us consider a piece of apparatus whose kilowatt flow may be in either direction. In Fig. 3 is a transformer connecting a 110-kv system with a 44-kv system. Assume the reactive kilovolt-ampere meter (conventional scale markings) is connected to indicate correctly for kilowatt flow from bus to transformer. Under the conventional method shown in Fig. 3(*a*) the meters indicate that 10,000 kw and 10,000 leading rkva are flowing from the 44-kv bus into the 44-kv side of the transformer. If the reactive kilovolt-ampere meter read "10,000" to the left of the zero point, the readings would be 10,000 kw and 10,000 lagging rkva flowing from the 44-kv bus into the 44-kv side of the transformer.

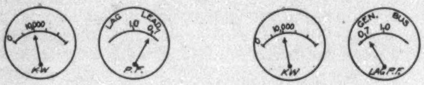

FIG. 4—ACADEMIC (a) AND PRACTICAL (b) USE OF TWO-QUADRANT POWER-FACTOR METERS

(a). 10,000 kw flowing from generator to bus. Leading reactive kilo-volt-amperes flowing from generator to bus. Ratio of kilowatts to total kilo-volt-amperes is 0.7

(b). 10,000 kw flowing from generator to bus. "Reactive kilowatts" flowing from bus to generator. Ratio of kilowatts to kilovolt-amperes is 0.7

In accordance with convention No. 1, previously stated, the markings on the reactive kilovolt-ampere meter will be changed to those shown in Fig. 3(*b*) the reactive kilovolt-ampere meter connections being reversed to produce this result. As before, the kilowatt meter indicates 10,000-kw flowing from bus to transformer. The *reactive kilowatt* meter indicates 10,000 *rkw* flowing from transformer to bus.

It should be noted that, in Fig. 3(*a*) correct reactive kilovolt-ampere meter readings can be obtained only when the reader knows how the reactive kilovolt-ampere meter is connected, i. e., for which direction of kilowatt flow the reactive kilovolt-ampere meter markings "lead" and "lag" apply. On the other hand, with the new *reactive kilowatt* meter markings shown in Fig. 3(*b*) the reader never has to worry about instrument connections.

### POWER-FACTOR METERS

Power-factor meters where already installed may be treated the same as *reactive kilowatt* meters, as is shown in the following paragraph.

A power-factor meter really indicates direction of *reactive kilowatt* flow. In this standardization, the instrument will *always* be a "lagging power-factor meter." In other words, it will always be used to indicate the direction of flow of (lagging) reactive power. At the same time, of course, its scale is so calibrated as to give the ratio of kilowatt to kilovolt-amperes, regardless of the relative directions of kilowatt and *reactive kilowatt* flow. In Figs. 4 and 5 are illustrations. To obtain consistent meter labelling requires reversal of the conventional connections of the power-factor meter in each case.

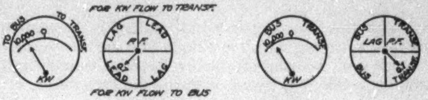

FIG. 5—ACADEMIC (a) AND PRACTICAL (b) USE OF FOUR-QUADRANT POWER-FACTOR METERS

(a). 10,000 kw from transformer to bus. Leading reactive kilovolt-amperes from transformer to bus. Ratio of kilowatts to total kilovolt-amperes is 0.7

(b). 10,000 kw from transformer to bus. "Reactive kilowatts" from bus to transformer. Ratio of kilowatts to kilovolt-amperes is 0.7

### LOG SHEETS AND DIAGRAMS

To illustrate the application of the conventions to log sheets, let us see how the readings of Fig. 3(*b*) would be recorded. The readings are 10,000 kw flowing from 44-kv bus to transformer and 10,000 *rkw* flowing from transformer to 44-kv bus. These readings would appear on the station log sheet as follows:

| Circuit | Kw | *Rkw* |
|---|---|---|
| 44-Kv Bus—Transformer No. 2 | → 10,000 | ← 10,000 |

The instrument readings pictured in Fig. 5 would be entered in a log sheet as follows:

| Circuit | Kw | Lag P.F. |
|---|---|---|
| Bus—Transformer No. 12 | ← 10,000 | → 0.7 |

If the log entry for the condition pictured in Fig. 3(*b*) was to be transferred to a system diagram it would be written as shown in Fig. 6. In this method, having standardized on lagging *reactive kilowatts*, in diagrams lagging *reactive kilowatts* will be positive and leading *reactive kilowatts* (if ever referred to) will be negative.

FIG. 6—APPLICATION OF PRACTICAL REACTIVE POWER TECHNIQUE TO DIAGRAMS

### VOLTAGE CONTROL

In a compact electrical system it is frequently possible to obtain satisfactory voltage control at substation busses by regulation of generator voltage. Generator voltage control will not, however, provide proper substation voltage regulation in an electrical system with long transmission lines. Additional facilities must be provided at some of the receiving substations to allow proper voltage control at these points. This voltage control is best provided in many cases by reactive power generators (synchronous condensers) at the receiving substations. In this application reactive power generators may be thought of as having two functions. One is the supply of the reactive power to the local load. This relieves the transmission system and power generators of the burden of the reactive power. The other function is that of sending reactive power back over the transmission circuits in the opposite direction for the purpose of voltage control. By this means a voltage gradient in one direction due to flow of active power may be compensated for by a gradient in the opposite direction due to flow of reactive power, thus making possible the maintenance of practically a flat voltage level over the whole system.

### CONSUMER METERING

In consumer metering we are concerned only with what is taking place at a certain point in the circuit, namely, the point of delivery to the customer, and not at all with the questions of sources and control. For this purpose therefore the "academic" approach and technique are applicable. Present practices in metering customers which take large amounts of reactive power in proportion to their consumption of active power, may in some cases leave something to be desired, but it is doubtful if independent metering of the active and reactive components of the customer's load would be justified in many cases, since present rates doubtless are adjusted to an average situation from which only a few instances would widely depart. An inexpensive means of measuring kilovolt-amperes directly or measuring the arithmetic difference between the kilovolt-amperes and the kilowatts may ultimately prove useful in this field.

### CONCLUSION

The "practical" conception of reactive power as herein outlined, in which the generation, metering, and control of active and reactive power are consciously divorced from each other, results in a simplified technique of power system operation which greatly facilitates the control of the system and the maintenance of maximum system efficiency.

## Discussion

For discussion of this paper see page 779.

# Power, Reactive Volt-Amperes, Power Factor

BY C. L. FORTESCUE*

Fellow A.I.E.E.

***Synopsis.***—*The relation between power, reactive volt-amperes, and power factor is discussed for sinusoidal electromotive forces and currents. Reactive volt-amperes is defined as the flow of stored energy into the circuit and is deduced from the stored energy cycle. It is shown to be a cyclic flow of power which is 90 deg in advance of the cyclic part of the dissipation or power input cycle which with the stored energy cycles is positive at all instants. This leads to the vector equation* $\breve{E}\mathring{I} + \bar{E}\breve{I}$ *derived for the equation of total inflow of energy given by* $Ri^2 + \frac{d}{dt}\left(\frac{1}{2}Li^2\right)$ *or* $\left(Ri^2 + L\frac{di}{dt}i\right)$ *for an inductive system or* $Ri_2 + \frac{d}{dt}\left(\frac{1}{2}\frac{q^2}{C}\right)$ *or* $\left(Ri + \frac{q}{C}\right)i$ *for a capacitor system.*

*Non-sinusoidal electromotive forces and currents are discussed and it is shown that there is no simple relation between the volt-amperes as obtained by voltmeters and ammeters and power as obtained by wattmeters and reactive power. The inflow of stored energy for double frequency fundamental can be obtained but it appears to bear little relation to the product of mean square volts and amperes and true average power. It is concluded that the ratio of power to mean square volt-amperes is a useful practical factor with non-sinusoidal waves encountered in practice but should not be used to define reactive volt-amperes.*

*Polyphase power and reactive volt-amperes are defined. In a balanced system power is continuous and the instantaneous reactive volt-amperes are zero. Nevertheless, a polyphase balanced system has a power factor which is the same as that of each phase. In an unbalanced system each symmetrical component has a power factor and in addition there is interchange of power between phases resulting from unbalance so that each phase has an individual power factor. It is shown that the positive phase sequence power and reactive volt-amperes, if the generator supplying power is symmetrical, include both the negative and positive phase sequence power and reactive volt-amperes; that is, the source of all power and stored energy is the positive sequence, and the positive phase sequence flow of energy gives the correct measure of the power factor of the system.*

*Non-linear circuits are characterized by frequency conversion. If such are supplied from a sinusoidal generator, all the harmonic power and reactive volt-amperes must be supplied from the fundamental frequency which is the source of the whole power and reactive volt-ampere output. Therefore, the fundamental frequency power and reactive volt-amperes properly define the true power factor of the system.*

## INTRODUCTION

THE current ideas regarding the relations between power, reactive volt-amperes, volt-amperes, and power factor were the outcome of an attempt to express the theory of electric circuits subjected to non-sinusoidal electromotive forces in terms of an equivalent sine wave. The equivalent sine wave of a non-sinusoidal wave is a sine wave having the same mean square value as the non-sinusoidal wave. In the elementary theory of electric circuits it was assumed that non-sinusoidal electromotive forces impressed on a linear electric system could be replaced by their equivalent sine waves without causing substantial error in the result, which implied that the wave form of the currents set up in the system was the same as that of the impressed electromotive forces. Later on engineers came to realize that this specification for non-sinusoidal waves was inadequate and another factor was introduced, namely, form factor which was defined as the ratio of maximum value of the actual wave to that of the equivalent sine wave. This factor did not help to any extent in defining the relations between volt-amperes, reactive volt-amperes, and power for non-sinusoidal waves, for the simple reason that these quantities are not definable by means of two factors.

## ELEMENTARY THEORY OF ENERGY FLOW RELATIONS IN LINEAR ELECTRIC CIRCUITS

A linear circuit, however complex, is defined as one in which an applied sinusoidal electromotive force will produce only sinusoidal currents. The characteristic of such a system or net is defined by the principle of superposition which for the present purpose may be stated as follows: If the connections of a linear net *remain unchanged* during the introduction of any electromotive forces in the net either simultaneously or in any sequence whatever, the resulting currents are the same as if each electromotive force were applied to the network at rest individually at the proper instant and the resulting currents superposed. Thus each electromotive force acts upon the system as if it were independent of all the others. The fact that the system must remain unchanged during the introduction of these electromotive forces has been emphasized for the reason that it is not always realized that the closing of a pair of terminals through a generator changes a network and, therefore, the principle of superposition no longer holds. In the case we are considering, however, it is supposed that certain electromotive forces are already established and they may be considered as having been introduced simultaneously or separately without any change in the network. Commercial systems are never strictly linear, on account of the presence of iron in the circuits of electric machines, but the effect of such non-linear elements in the system in general may be ignored. There are cases, however, where they become of importance, such as, for example, cases of telephone interference. In such cases each harmonic must be considered independently with reference to its source.

If we consider a linear system in which all the elements consist of resistance and self-inductance with a sinusoidal electromotive force impressed, the relations between volt-amperes, power, and reactive volt-amperes are expressed as follows where $E$ and $I$

---

*Consulting Transmission Engineer, Westinghouse Electric and Manufacturing Co., East Pittsburgh, Pa.

*Presented at the North Eastern District Meeting of the A.I.E.E., Schenectady, N. Y., May 10–12, 1933.*

are the root mean square values of electromotive force and current

$$\left.\begin{aligned} \text{Electromotive force} &= E\cos\omega t \\ \text{Current} &= I\cos(\omega t-\alpha) \\ \text{Volt-amperes} &= EI \\ \text{Power} &= EI\cos\alpha \\ \text{Reactive Volt-amperes} &= EI\sin\alpha \end{aligned}\right\} \quad (1)$$

We may represent the electromotive force $E\cos\omega t$ by two equal vectors of length equal to one-half the mean square value, one rotating positively the other negatively, denoting the positively rotating vector $\check{E}$ and the negatively rotating vector by $\hat{E}$

$$\begin{aligned} e &= \sqrt{2}\,E\cos\omega t = \frac{\check{E}+\hat{E}}{\sqrt{2}} = \frac{Ee^{j\omega t}+Ee^{-j\omega t}}{\sqrt{2}} \\ i &= \sqrt{2}\,I\cos(\omega t-\alpha) = \frac{\check{I}+\hat{I}}{\sqrt{2}} = \frac{Ie^{(j\omega t-\alpha)}+Ie^{-(j\omega t-\alpha)}}{\sqrt{2}} \qquad (2) \\ ei &= \frac{\check{E}\hat{I}+\hat{E}\check{I}}{2}+\frac{\check{E}\check{I}+\hat{E}\hat{I}}{2} \end{aligned}$$

In the vector representation of electromotive forces and currents the convention is to use the positively rotating vectors $E$ and $I$. It will be observed that $\check{E}$ and $\check{I}$ enter into the expression for $ei$ symmetrically and therefore with equal authority. On the other hand in practical problems $\check{E}$ is the known function of the independent variable $t$ while $\check{I}$ is the dependent function, it would therefore seem consistent to define energy flow into the circuit by

$$P + jQ = \check{E}\hat{I} \qquad (3)$$

This convention is seen also to be consistent with the d-c analogy; namely, since the impedance $Z$ in an a-c system takes the place of resistance $R$ in a d-c system then

$$\left.\begin{aligned} &\text{Direct current} \begin{cases} E = RI \\ \text{Power} = EI = RI^2 \end{cases} \\ &\text{Alternating current} \begin{cases} \check{E} = Z\check{I} \\ P + jQ = \check{E}\hat{I} = ZI^2 \end{cases} \end{aligned}\right\} \quad (3)$$

The above arguments, logical as they appear to the writer, may not be convincing to some. For such it will be necessary to deduce the equation of flow of energy into a circuit from the equation of energy. In a circuit having resistance and inductance in series the rate of dissipation of energy or power is

Dissipation $= Ri^2$
The kinetic energy is

$$T = \frac{1}{2}Li^2$$

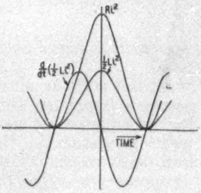
Therefore, the flow of energy is

$$Ri^2 + \frac{d}{dt}\left(\frac{1}{2}Li^2\right) \quad \text{or} \qquad (4)$$

$$\left(Ri + L\frac{di}{dt}\right)i \qquad (5)$$

Now a little consideration will convince any one familiar with dynamical systems that the instant at which the kinetic energy reaches a maximum must coincide with the instant of maximum dissipation of energy through friction, and the epoch of maximum rate of storage must necessarily take place prior to that of maximum storage and therefore prior to that of maximum rate of dissipation. In a non-conservative system constrained to move under a sinusoidal force the cycle of stored energy in the system coincides in phase with the cycle of energy rate of dissipation; the total kinetic energy is always positive. The rate at which energy is stored into the system or the work done by the force in producing motion against the inertia of the system is $\frac{d}{dt}\left(\frac{1}{2}Li^2\right)$. The maximum inflow of stored energy therefore occurs when the stored energy is one-half its maximum and increasing, and therefore when the rate of dissipation is one-half its maximum value and increasing, and the maximum outflow of stored energy occurs at the same point of the stored energy cycle when it is decreasing, that is at the same point of the decreasing dissipation cycle. The cycle of inflow of stored energy is therefore in *phase advance* of the cycle of dissipation or power inflow by a right angle.

These cyclic flow of energy relations are shown in Fig. 1, as expressed by eq 4 and in Fig. 3 for those who are happier when dealing with electromotive forces and currents these relations are shown as expressed by eq 5.



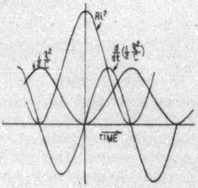


FIG. 1 (LEFT)—FLOW OF ENERGY RELATIONS AS EXPRESSED BY EQ 4 FOR RESISTANCE AND INDUCTANCE IN SERIES

FIG. 2 (RIGHT)—FLOW OF ENERGY RELATIONS AS EXPRESSED BY EQ 6 FOR RESISTANCE AND CAPACITY IN SERIES

For a circuit having potential energy, the stored energy is

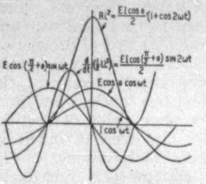
$$W = \frac{1}{2}\frac{q^2}{C}$$

where $q$ is the change at any instant and $C$ is the capacity. The inflow of energy into the system is given by

$$Ri^2 + \frac{d}{dt}\left(\frac{1}{2}\frac{q^2}{C}\right) \quad \text{or} \qquad (6)$$

$$\left(Ri^2 + \frac{q}{C}\right)i \qquad (7)$$

In the dynamical analogy $q$ is the coördinate of the motion, $i$ is the velocity. Starting with maximum velocity at time zero, the spring (supposed to be linear) will have reached $^1/_2$ its maximum deflection and the maximum stored energy will occur when the velocity becomes zero, that is, when $Ri^2$ is zero. Thus the cycle of energy storage is of exactly the same form as that of the rate of dissipation of energy but lagging 180 deg. Therefore, the cycle of inflow of potential energy $\frac{d}{dt}\left(\frac{1}{2}\frac{q^2}{C}\right)$ will lead the energy storage cycle by 90 deg and will lag the rate of energy dissipation cycle by 90 deg. In Fig. 2 is shown this expressed in terms of the dissipation and stored energy cycle as given by eq 6, and in Fig. 4 in terms of current and electromotive forces as in eq 7.



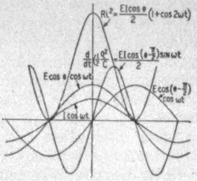


Fig. 3 (Left)—Flow of Energy Relations as Expressed by Eq 5 for Resistance and Inductance in Series

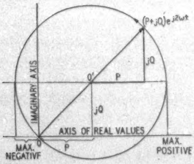
Fig. 4 (Right)—Flow of Energy Relations as Expressed by Eq 7 for Resistance and Capacity in Series

In dealing with cyclic quantities such as alternating currents and electromotive forces the convention has been standardized of representing such quantities by positively rotating vectors in the complex plane, the projection of these vectors on the real axis giving the instantaneous value or, where $\check{E}$ and $\hat{I}$ are root mean square, the instantaneous values divided by $\sqrt{2}$. The only difference between energy flow values and currents and electromotive forces is that the axis of rotation of the former is displaced from the origin by the amount $P + jQ = \check{E}\hat{I}$ which gives the mean power or rate of dissipation as the abscissa and the value of the rate of energy storage which is a purely sinusoidal quantity as ordinate. The rotating vector is the quantity $\check{E}\hat{I}\ e^{j2\omega t}$ rotating about the displaced axis of rotation which since at $t = 0$, $\check{I}$ and $\hat{I}$ are both wholly real gives $\check{E}\hat{I}\ e^{j2\omega t} = \check{E}\hat{I}$.



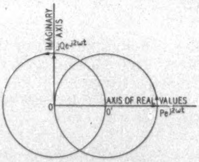


Fig. 5 (Left)—Vector Diagram of Instantaneous Energy Flow as Expressed by Eq 8 for Resistance and Inductance in Series

Fig. 6 (Right)—Vector Diagram of Component Power and Reactive Volt-Amperes as Expressed by Eq 9 for Resistance and Inductance in Series

The instantaneous power vector diagram therefore is properly expressed by

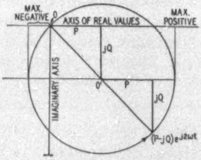
$$ei = \left.\begin{array}{l}\text{real part of } \check{E}\hat{I} + \check{E}\hat{I}, \text{ or}\\ \check{E}\hat{I}(1 + e^{j2\omega t}), \text{ or}\\ (P + jQ)(1 + e^{j2\omega t})\end{array}\right\} \quad (8)$$

If it is desired to obtain the diagram in terms of the cyclic components of $P$ and $jQ$ we should leave $jQ$ out in the last equation, since it is stationary and its projection on the real axis is zero. This gives the expression:

$$ei = P(1 + e^{j2\omega t}) + jQe^{2\omega t} \quad (9)$$

where $P$ is the real part of $\check{E}\hat{I}$ and $jQ$ its imaginary part.

These two diagrams are given in Figs. 5 and 6. The diagram of Fig. 5, following eq 8, may be called the *instantaneous energy flow vector diagram,* while Fig. 6, following eq 9, may be called the *component power and reactive volt-ampere vector diagram.* The sum of the projections of Fig. 6 on the real axis corresponds in value and time with the projections of Fig. 5 on the real axis. These diagrams are based on circuits having kinetic energy in operation. Similar diagrams for circuits having potential energy are shown in Figs. 7 and 8, and the same eqs 8 and 9 apply, $Q$ in this case being negative.



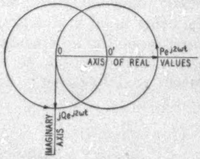


Fig. 7 (Left)—Vector Diagram of Instantaneous Energy Flow as Expressed by Eq 8 for Resistance and Capacity in Series

Fig. 8 (Right)—Vector Diagram of Component Power and Reactive Volt-Amperes as Expressed by Eq 9 for Resistance and Capacity in Series

In eq 4 if we take $i = I\cos\omega t$, where $I$ is the maximum instantaneous value of $i$,

$$\begin{aligned} Ri^2 &= RI^2\cos^2\omega t\\ &= \frac{RI^2}{2} + \frac{RI^2}{2}\cos 2\omega t\\ {}^1/_2\,Li^2 &= \frac{1}{2}LI^2\cos^2\omega t\\ \frac{d}{dt}\left(\frac{1}{2}Li^2\right) &= -\omega LI^2\cos\omega t\sin\omega t\\ &= -\frac{1}{2}LI^2\sin 2\omega t\\ &= \frac{1}{2}LI^2\cos\left(2\omega t + \frac{\pi}{2}\right)\end{aligned}$$

Flow of energy

$$= \frac{RI^2}{2} + \left\{\frac{RI^2}{2}\cos 2\omega t + \omega\frac{LI^2}{2}\cos\left(2\omega t + \frac{\pi}{2}\right)\right\} \quad (10)$$

$$= \frac{RI^2}{2} + \left(\frac{RI^2}{4} + j\omega\frac{LI^2}{4}\right)e^{j2\omega t} +$$

$$\left(\frac{RI^2}{4} - j\omega\frac{LI^2}{4}\right)e^{-j2\omega t}$$

$$= \left\{\left(\frac{RI^2}{4} + j\omega\frac{LI^2}{4}\right) + \left(\frac{RI^2}{4} + j\omega\frac{LI^2}{4}\right)e^{j2\omega t}\right\} +$$
$$\left\{\left(\frac{RI^2}{4} - j\omega\frac{LI^2}{4}\right) + \left(\frac{RI^2}{4} - j\omega\frac{LI^2}{4}\right)e^{-j2\omega t}\right\}$$

Choosing positive rotation for vector representation of power we have

$$\begin{aligned}\text{Flow of energy} &= \frac{RI^2}{2} + j\omega\frac{LI^2}{2} + \left(\frac{RI^2}{2} + j\omega\frac{LI^2}{2}\right)e^{j2\omega t}\\ &= \check{E}\hat{I} + \check{E}\hat{I}e^{j2\omega t} \qquad (11)\\ &= \check{E}\hat{I} + \check{E}\check{I}\end{aligned}$$

Eqs 9 and 10, and the component circle diagram Fig. 6 correspond. Eqs 8 and 11 are those for Fig. 7 which is a single circle diagram giving the instantaneous power or flow of energy.

## SINGLE PHASE NON-SINUSOIDAL ELECTROMOTIVE FORCES AND CURRENTS

In the solution of linear circuits with non-sinusoidal electromotive forces applied it was shown that each harmonic of electromotive force is considered independent of the fundamental electromotive force and the other harmonics. Each harmonic therefore has its own power input, stored energy cycle, reactive volt-amperes, and power factor as if the others did not exist. If we consider the harmonic reactive volt-amperes with respect to the fundamental reactive volt-amperes, it is seen that the integral of the even harmonics over one-half cycle of the fundamental reactive volt-amperes is always zero, and for the odd harmonics will vary from zero up to the integral of one-half a harmonic reactive cycle. The amount added to the reactive volt-amperes during $^1/_2$ cycle of fundamental reactive volt-amperes for each harmonic is zero for all even and zero to $\pm\frac{1}{\pi}$ the integral over $^1/_2$ cycle of the odd harmonic, depending upon the phase position with respect to the fundamental reactive volt-ampere cycle. The contribution to the fundamental reactive volt-ampere cycle of the harmonic therefore is indeterminate from the root mean square volts and amperes showing that there is no such thing as the equivalent sine wave for non-sinusoidal currents and electromotive forces.

If the wave form of applied electromotive force is known the stored energy cycle for the fundamental component current and its harmonics are completely defined, and therefore the respective power inputs, reactive volt-amperes, and instantaneous powers are known for each harmonic and the whole instantaneous power cycle and fundamental reactive volt-ampere cycle can be obtained by composition of their individual values as pointed out, but the values obtained in this way cannot be derived from the mere measurement of the root mean square volts and amperes of the circuit.

In practical circuits the distortion is usually negligible and therefore power factor as defined should be retained as a convenient practical measure of the ratio of mean volt-ampere to mean power input or mean rate of dissipation. For analytical work where harmonics are large in comparison with the fundamental, equivalent sine waves should never be used, but each harmonic should be considered independently.

## POWER AND REACTIVE VOLT-AMPERES IN A SINGLE-PHASE LINEAR NETWORK

The method of obtaining power and reactive volt-amperes for a linear single-phase network may be generalized by using the Lagrangian energy function and Rayleigh dissipation function. If $i_1$, $i_r$, $i_n$ are the instantaneous currents flowing into $n$ terminals of the network and if it is supposed that the Lagrangian function $T-W$ (where $T$ is kinetic energy and $W$ is potential energy) and the dissipation function $F$ have been expressed in terms of the terminal currents, then

$$\text{Instantaneous power input at } r^{th} \text{ terminal} = i_r\frac{\delta F}{\delta i_r}$$

$$\text{Instantaneous inflow of stored energy} = \left(\frac{d}{dt}\frac{\delta(T-W)}{\delta i_r} - \frac{\delta(T-W)}{\delta q_r}\right)i_r$$

$$\text{Instantaneous power input} = \left\{\frac{\delta F}{\delta i_r} + \frac{d}{d_t}\frac{\delta(T-W)}{\delta i_r} - \frac{\delta(T-W)}{\delta q_r}\right\}i_r$$

This expression is quite general and applies for both sinusoidal and non-sinusoidal currents, and when the terminals supply induction motors and synchronous motors as well as simple impedances. For sinusoidal waves it gives the same result as the vector expression

$$P_r + jQ_r = \check{E}_r\hat{I}_r + \check{E}_r\check{I}_r$$

which has been shown to be the vector representation of instantaneous power.*

## POWER, REACTIVE VOLT-AMPERES, AND POWER FACTOR OF POLYPHASE CIRCUITS

It is not necessary to consider the general polyphase system. It is sufficient for practical purposes to deal with the three-phase system. Here as shown in "Polyphase Power Measurements" by C. L. Fortescue, A.I.E.E. TRANS., v. 42, 1923, p. 358–71, the system if sinusoidal can be completely characterized by the use of the sequence symbols $S^0$, $S^1$, $S^2$, and the conjugate symbols $S^0$, $S^{-1}$, $S^{-2}$, the zero sequence system being self conjugate. Thus the currents are given in all phases by

$$S^0\check{I}_{A0} + S^1\check{I}_{A1} + S^2\check{I}_{A2}$$

---

*In ordinary linear networks the total inflow of stored energy can be expressed simply as follows:

$$\text{Total instantaneous inflow of stored energy} = \frac{dT}{dt} + \frac{dW}{dt}.$$

The portion of this to be assigned to the $r$th terminal is that part of $\frac{dT}{dt}$ containing $i_r$ and that part of $\frac{dW}{dt}$ containing $q_r$. For the instantaneous power input at the $r$th terminal the quantity $\frac{\delta F}{\delta i_r}$ must be added.

$A$ being the principal phase, and the electromotive force

$$S^0\breve{E}_{A0} + S^1\breve{E}_{A1} + S^2\breve{E}_{A2}$$

Power as in single-phase circuits is defined by $\breve{E}\hat{I}$ so that total power is

$$\Sigma(S^0\breve{E}_{A0} + S^1\breve{E}_{A1} + S^2\breve{E}_{A2})\quad(S^0\hat{I}_{A0} + S^{-1}\hat{I}_{A1} + S^{-2}\hat{I}_{A2})$$

which gives

$$\begin{aligned}&3(\breve{E}_{A0}\hat{I}_{A0} + \breve{E}_{A1}\hat{I}_{A1} + \breve{E}_{A2}\hat{I}_{A2}) +\\ &\Sigma(S^{-1}\breve{E}_{A0}\hat{I}_{A1} + S^{-2}\breve{E}_{A0}\hat{I}_{A2} + S^1\breve{E}_{A1}\hat{I}_{A0} + S^2\breve{E}_{A2}\hat{I}_{A0}) +\\ &\Sigma(S^{-1}\breve{E}_{A1}\hat{I}_{A2} + S^1\breve{E}_{A2}\hat{I}_{A1})\end{aligned}$$

The instantaneous sum of the expressions having $S^{-1}$, $S^{-2}$, $S^1$, and $S^2$ preceding them is zero. They are the quantities which define the interchange of power and reactive volt-amperes among phases. This is characteristic of unbalanced polyphase systems and unbalance factors are associated with those interchanges.

If we take the product

$$(S^0\breve{E}_{A0} + S^1\breve{E}_{A1} + S^2\breve{E}_{A2})\quad(S^0\check{I}_{A0} + S^1\check{I}_{A1} + S^2\check{I}_{A2})$$

we obtain

$$\begin{aligned}&\Sigma S^2\breve{E}_{A1}\check{I}_{A1} + S^1\breve{E}_{A2}\check{I}_{A2}\\ &\Sigma S^1\breve{E}_{A0}\check{I}_{A1} + S^2\breve{E}_{A0}\check{I}_{A2} +\\ &\quad 3\breve{E}_{A0}\check{I}_{A0} + 3(\breve{E}_{A1}\check{I}_{A2} + \breve{E}_{A2}\check{I}_{A1})\end{aligned}$$

It will be observed that the first term is the total inflow of reactive volt-amperes for each balanced system comprising the symmetrical coördinates, except the zero sequence term, and these are zero since they are preceding by $S^1$ and $S^2$ showing that the total flow of energy is uniform in a balance system. The terms $3\breve{E}_{A0}\check{I}_{A0} + 3(\breve{E}_{A1}\check{I}_{A2} + \breve{E}_{A2}\check{I}_{A2})$ are connected with the interchange of power and reactive power between phases and it is seen that these double frequency products are not zero. The flow of power in an unbalanced polyphase system is not uniform. The equation gives the average power factor of each symmetrical component of an unbalanced system and of course if the system is balanced, zero and negative sequence are not present and the expression $\Sigma S^0\breve{E}_{A1}\hat{I}_{A1} = 3\breve{E}_{A1}\hat{I}_{A1}$ gives not only the mean power but also the reactive volt-amperes which divided by three is the reactive volt-amperes per phase. Space does not permit of going exhaustively into the subject of polyphase power and reactive volt-ampere measurements but the following important points should be noted.

1. In a balanced system the total instantaneous reactance volt-amperes is zero. The volt-amperes per phase are given by the imaginary part of the product $3\breve{E}_{A1}\hat{I}_{A1}$.

2. In an unbalanced system there are three such products representing power and reactive volt-amperes of each symmetrical component.

3. In an unbalanced system supplied from a symmetrical generator the total power and reactive volt-amperes including that of the negative and zero sequence components are included in the positive sequence components so that the expressions $3\breve{E}_{A1}\hat{I}_{A1}$ gives the true measure of power and reactive volt-amperes that is supplied by the generators. The individual power factor per phase of each generator must be obtained by computing the total current and total electromotive force for each phase in the regular way.

## NON-LINEAR CIRCUITS

The analysis of non-linear circuits is complicated mathematically so only a brief sketch of the main characteristics will be given. The fundamental characteristic of such circuits is that sinusoidal power taken in is partly absorbed as such and partly converted into harmonic power which is either dissipated in the system or made use of. Examples of non-linear circuits are:

1. Magnetizing circuit of transformers and other electrical apparatus using iron.
2. Mercury arc and thermionic rectifier.
3. Power arcs.

If all the power for such networks is supplied from a sinusoidal source, the total power and reactive volt-amperes delivered will be given by the power and reactive volt-ampere input of the fundamental sinusoidal impressed electromotive force.

## CONCLUSIONS

Following are conclusions which may be drawn:

1. For a sine wave the dissipation cycle and the stored energy cycle are fundamental concepts and are easily obtained. The power input is given by the dissipation cycle and the inflow of stored energy by the differential with respect to time of the stored energy cycle. The sum of these three cycles gives the instantaneous power cycle. The vector expression for this is $\breve{E}\hat{I} + \breve{E}\check{I}$ the second term being double frequency. $\breve{E}\hat{I}$ being equal to $P + jQ$ gives the proper point on the complex plane for the center of rotation of the positively rotating vector $\breve{E}\check{I}$.

2. In 3 phase sinusoidal balanced systems the total power input from a generator is continuous. The total reactive volt-amperes is zero but per phase it is given by $\breve{E}_{A1}\hat{I}_{A1} + \breve{E}_{A1}\check{I}_{A1}$ vectorially. When there is unbalance the polyphase power input at an unbalanced terminal is given by $3(\breve{E}_{A1}\hat{I}_{A1} + \breve{E}_{A2}\hat{I}_{A2} + \breve{E}_{A0}\hat{I}_{A0})$. If the source of power is a symmetrical machine the total power and reactive volt-amperes input including the power and reactive volt-amperes circulated in the system by the zero and negative sequence components are given by $3\breve{E}_{A1}\hat{I}_{A1}$, and this gives the true power and reactive volt-amperes input to the system.

3. Non-linear circuits are characterized by frequency changing so that fundamental power and reactive volt-amperes are taken in and converted into power and reactive volt-amperes at higher or lower frequencies. Here again in general the power and reactive volt-amperes measured at fundamental frequency define the true power and reactive volt-amperes supplied by the sine wave generator.

## Discussion

For discussion of this paper see page 779.

# Reactive Power and Power Factor

BY W. V. LYON[1]

Fellow, A.I.E.E.

It is the purpose of this paper to discuss the terms, reactive power and power factor; to see if they may be defined by some general mathematical principles so that when so defined they will be useful in the calculation of electric circuits; and to see what limits there are, if any, to a physical interpretation of these mathematical definitions.

The value of a steady alternating electromotive force, $e$, or current, $i$, is mathematically defined as its root mean square value:

$$E_{rms} = \sqrt{\frac{1}{T}\int_0^T e^2\,dt} \text{ volts}$$

$$I_{rms} = \sqrt{\frac{1}{T}\int_0^T i^2\,dt} \text{ amperes}$$

where $T$ is the time of one cycle, *i.e.*, the reciprocal of the frequency.

The mathematical definition of the power, $P$, supplied to a circuit, where the potential across the circuit and the current through it are $e$ and $i$ is:

$$P = \sqrt{\frac{1}{T}\int_0^T ei\,dt} \text{ watts}$$

The advantages of these definitions of electromotive force, current and power have long been recognized by international agreement. Recently it has likewise been agreed that reactive power shall be defined mathematically by the expression $EI \sin \theta$; where $E$ is the root mean square magnitude of the sinusoidal potential (volts) across the circuit, $I$ is the root mean square magnitude of the sinusoidal current (amperes) in the circuit, and $\theta$ is their relative phase. It was further agreed that the unit of reactive power shall be the "var." The total reactive power supplied to a network is the algebraic sum of the reactive powers supplied to its branches. It is thus highly desirable that an agreement should be reached in regard to the sign of the angle $\theta$; that is, whether $\theta$ is to be taken as positive for condensive or for inductive loads. In other words, whether the reactive power is to be positive for a condensive or for an inductive load. In this paper the author has assumed that the angle $\theta$ is *positive* when the current *leads* the potential across the circuit, and *negative* when it *lags*. Some have adopted the opposite convention.

The limitation of a sinusoidal time variation for the potential and current in the present definition of reactive power is unnecessary. The reactive power may be more broadly defined as $\Sigma E_h I_h \sin \theta_h$; where $h$ represents the order of the individual harmonics in the potential and current. That is, the total reactive power for any circuit may be defined as the sum of the reactive powers in the circuit due to the different harmonic components of potential and current. This latter definition of reactive power is not limited by the wave form of the applied electromotive force or by the constancy of the circuit "constants" or, in polyphase cases, by the number of the phases or their symmetry. It is as broad as and corresponds to the accepted definition of (active) power which in the case of non-sinusoidal potentials and currents can be expressed as $\Sigma E_h I_h \cos \theta_h$. Hereafter this definition of reactive power, $\Sigma E_h I_h \sin \theta_h$, will be referred to as the "mathematical definition."

In what follows, except as noted, the letters $E$, $I$, and $S$ are vector quantities whose values may be given by complex numbers. Addition and multiplication are subject to the rules which apply to complex numbers. When necessary, the magnitude of the potential vector, $E$, is indicated thus: $|E|$.

### VECTOR VOLT-AMPERES

If a sinusoidal electromotive force, represented by the vector, $E$, is applied to a circuit and the resulting current is also sinusoidal and is represented by the vector, $I$, the vector volt-amperes, $\underset{\smile}{E}I$, are

$$\underset{\smile}{E}I = P + jQ \text{ (See footnote 2.)} \qquad (1)$$
$$P = |E| \times |I| \cos\theta \text{ watts}$$
$$Q = |E| \times |I| \sin\theta \text{ vars}$$

where $\theta$ is the phase angle by which the current leads the electromotive force. $P$ and $Q$ are the active and reactive powers. This expression, $\underset{\smile}{E}I$, for the vector volt-amperes is a very useful one in circuit analysis. It is a non-rotating vector and is in this respect quite different from the rotating vectors which represent the potential and current. Due to its non-rotating character, vector volt-amperes due to a potential and current of one frequency may be added to the vector volt-amperes due to a potential and current of another frequency, and the result will be a fixed vector. It must

---

[1] Professor of Electrical Machinery, Massachusetts Institute of Technology, Cambridge, Mass.

*Presented at the North Eastern District Meeting of the A.I.E.E., Schenectady, N. Y., May 10-12, 1933.*

[2] $\underset{\smile}{E}$ is the conjugate of $E$ with respect to the horizontal axis, *i. e.*, the axis of reals. If

$$E = |E|\,\overline{/\omega t}$$
$$\underset{\smile}{E} = |E|\,\overline{/-\omega t}$$

and $$I = |I|\,\overline{/\omega t + \theta}$$

Then $$\underset{\smile}{E}I = |E| \times |I|\,\overline{/\theta}$$
$$= |E| \times |I|\,(\cos\theta + j\sin\theta)$$
$$= P + jQ$$

where $$P = |E| \times |I| \cos\theta \text{ watts}$$
$$Q = |E| \times |I| \sin\theta \text{ vars}$$

be borne in mind that reactive power as well as active power depends only upon potentials and currents of the same frequency. If several frequencies are present simultaneously, both of these powers are computed for each frequency separately as if the other frequencies did not exist; that is, potential of one frequency and current of another frequency produce neither active nor reactive power.

### TOTAL VECTOR VOLT-AMPERES

There is an important mathematical theorem in circuit analysis of which, apparently, no formal proof has been given. It is, that the sum of the vector volt-ampere inputs to the individual branches of any network whatsoever equals the vector volt-ampere input at the terminals of the network. In the general case, when the potentials and currents are non-sinusoidal, each harmonic order may be considered separately, since they have no effect upon each other in the vector volt-amperes. First it is evident that the total vector volt-ampere input at the terminals of any series or parallel combination is not affected by replacing the combination by its equivalent single circuit. The key to the proof, however, is the star-mesh transformation.[3] It may be shown that the total vector volt-ampere input at the terminals of any star is not affected by replacing the star by its equivalent mesh. In these replacements the impedance of any branch of the original network at the frequency being considered is the *ratio of the potential vector to the current vector* for that branch and at the frequency considered. In the analysis it is only necessary to specify what these ratios are and not to describe how they may be obtained by physical circuits. In the case of non-linear circuits it may be necessary for these impedances to assume values of zero and infinity. If in any branch there is a harmonic component of current without any corresponding component of potential, the coefficient, $z$, for that branch is zero; and similarly, if there is a harmonic component of potential without a corresponding component of current, the coefficient, $z$, for the branch is infinite. The series, the parallel, and the star-mesh transformations are still valid even in these extreme cases.

By means of these transformations any network can be reduced to a single circuit or circuits connecting its input terminals. This process does not alter the total vector volt-amperes, and thus the theorem is proved in the case of a single frequency. Since it is true for one frequency it is also true in the general case where the potentials and currents are non-sinusoidal. Thus the theorem may be expressed in the general formula:

Total vector volt-ampere ($E_0 I_0$) input to any network is

$$\underset{\wedge}{E}_0 I_0 = \sum_{h=1}^{h=m} \sum_{k=1}^{k=n} \underset{\wedge}{E}_{hk} I_{hk} \qquad (2)$$

where $h$ is the harmonic order of potential and current and there are $n$ branches in the network. The summation is made for all of the harmonic orders in all of the branches.

The foregoing proof involves only the potential and current vectors and no restriction is placed upon them except that they must obey the two Kirchhoff laws that $\Sigma E$ about any closed loop is zero and that $\Sigma I$ at any point is also zero. The real part of the total vector volt-amperes to any branch, $\Sigma \mid E_h \mid \times \mid I_h \mid \cos \theta_h$, is the total power supplied to that branch. It is not illogical then to name the imaginary part, $\Sigma \mid E_h \mid \times \mid I_h \mid \sin \theta_h$, the reactive power supplied to that branch. It should be emphasized that this definition of reactive power is based on the relation of the *terminal* potential of any branch and the *current* in the branch. It in no way inquires into the cause of this relation and so does not attempt to correlate the "reactive power" and any of the physical reactions within the branch. The physical concept of (active) power is perfectly definite. Unfortunately, however, there is, apparently, no general physical concept of reactive power. It is true that reactive power is due to the displacement between the potential and current produced by the physical characteristics of the circuit. The displacement is frequently caused by the magnetic and electric fields and thus there has grown a belief that there is a direct relation between the reactive power and the power delivered to, or energy stored in, these fields. Since the displacement may be produced by other physical characteristics, the physical conception of reactive power based on the magnetic and electric fields cannot be general. Moreover, as we shall presently show, this conception may lead to erroneous conclusions. Reactive power is fundamentally a mathematical quantity which is useful in circuit analysis. It is for this reason that its definition has been labeled "mathematical."

### POWER PULSATION

Before we attempt to identify the reactive power defined in this manner with any physical characteristic of the circuit, there is a variation of the mathematical theorem that is worth while considering. It will be noticed that the theorem holds equally well when the vectors, $E$, are substituted for their conjugates; that is, for any single frequency we may write:

$$E_0 I_0 = \sum_{k=1}^{k=n} E_k I_k \qquad (3)$$

The product $EI$ has a particular and useful significance. If the potential across any branch is:

$$e = \sqrt{2} \mid E \mid \sin (\omega t + \alpha)$$

---

[3] "Direct Capacity Measurement," G. A. Campbell, *Bell Sts. Tech. Jour.*, v. 1, July 1922, p. 18.

"A New Network Theorem," A. Rosen, *Jour. I.E.E.*, v. 62, 1925.

and the current in this branch is:

$$i = \sqrt{2}\,|I|\sin(\omega t + \alpha + \theta)$$

then the instantaneous power, $p$, is:

$$p = |E| \times |I| \cos\theta - |E| \times |I| \cos(2\omega t + 2\alpha + \theta)$$

or

$$p = |E| \times |I| \cos\theta - |E| \times |I| \sin(2\omega t + 2\alpha + \theta + 90^\circ)$$

Thus the double frequency portion of the instantaneous power can be represented by the vector product, $-jEI$. (See footnote 4.) This double frequency portion of the power will be called the power pulsation and it will be represented by the letter, $S$, (sinusoidal). Thus:

$$S = -jEI \tag{4}$$

Equation (3) may then be written

$$S_0 = \sum_{k=1}^{k=n} S_k = -j \sum_{k=1}^{k=n} E_k I_k \tag{5}$$

Since the total instantaneous power input is equal to the sum of the instantaneous powers absorbed by the various branches of the network, and since the same relation also holds for the average values of the power, the total power pulsation must be equal to the sum of the power pulsations in the various branches of the network. If there are harmonics present in the potentials and currents, the instantaneous power will contain terms that are the product of potentials and currents of different frequencies, and thus equation (3) cannot be extended to include the case where harmonics are present, as can be done with equation (2) for the vector volt-amperes.[5]

When the potentials and currents are both sinusoidal and of the same frequency, equations (2) and (5) can be combined in the following manner to obtain a check on the circuit calculations: Let

$$E_k = E_k' + jE_k''$$

and

$$I_k = I_k' + jI_k''$$

And similarly let

$$E_0 = E_0' + jE_0''$$

and

$$I_0 = I_0' + jI_0''$$

Then

$$E_k I_k = E_k' I_k' - E_k'' I_k'' + j\,(E_k' I_k'' + E_k'' I_k')$$

Also

$$\underset{\wedge}{E}_k I_k = E_k' I_k' + E_k'' I_k'' + j\,(E_k' I_k'' - E_k'' I_k')$$

If these results are substituted in equations (2) and (5) it at once follows that:

$$E_0' I_0' = \Sigma\, E_k' I_k'$$
$$E_0'' I_0'' = \Sigma\, E_k'' I_k'' \tag{6}$$
$$E_0' I_0'' = \Sigma\, E_k' I_k''$$

and

$$E_0'' I_0' = \Sigma\, E_k'' I_k'$$

The usefulness of these relations is apparent when we consider a typical problem. Let us suppose that the current input to a network due to the application of a potential $E_0' + j0$ is $I_0' + jI_0''$. Further let us suppose that in the solution of this problem we have determined the complex expressions for the potential and current for each branch of the network. The sum of the products of the imaginary component of each of these potentials and the real component of the corresponding current over the whole network should be zero, as shown by the fourth relation. The other relations are interpreted in a similar manner.

There is another important relation that results from this "mathematical" definition of reactive power. The sum of the squares of the active and reactive powers is in general equal to the square of the effective volts multiplied by the square of the effective amperes only when the potential and current are sinusoidal and of the same frequency. When there are harmonics present in either the potential or current, or in both simultaneously, this relation is in general not true. Or it may be stated that the magnitude of the vector volt-amperes, *viz.*, $\sqrt{P^2 + Q^2}$ does not equal the product of the effective volts and the effective amperes when there are harmonics present. For example, it would be found when testing a power transformer on open circuit that the difference between these quantities might well be as much as 8 per cent.

## PHYSICAL CONCEPT OF REACTIVE POWER

We will now examine three of the physical concepts of reactive power which connect it with the electric and magnetic fields.

*I. Concept of Instantaneous Reactive Power.* We shall define the instantaneous value of the reactive power supplied to a magnetic field by the electric circuit as the product of the instantaneous value of the current in the circuit and the instantaneous value of the electromotive force generated in the circuit by the time variation of the magnetic field. Similarly, the instantaneous value of the reactive power supplied to an electric field, *i.e.*, to a perfect condenser, equals the product of the instantaneous value of the current in the condenser and the instantaneous value of the potential across the terminals of the condenser. In other words, the instantaneous value of the reactive power is the time variation of the instantaneous value of the energy stored in the magnetic and electric fields. If the instantaneous value of the reactive power is zero, the stored energy is constant. If the potential and current are both sinusoidal the instantaneous reactive power is also sinusoidal but of double frequency. Care must be

---

[4]
$$\begin{aligned} EI &= |E|\,\underline{/\omega t + \alpha}\;|I|\,\underline{/\omega t + \alpha + \theta} \\ &= |E| \times |I|\,\underline{/2\omega t + 2\alpha + \theta} \\ jEI &= |E| \times |I|\,\underline{/2\omega t + 2\alpha + \theta + 90^\circ} \end{aligned}$$

[5] The mathematical formula can be extended to include harmonics, but it cannot be interpreted as pulsating power, since the pulsating power will contain terms which are the product of potential of one frequency and current of a different frequency.

observed in distinguishing between the terms "instantaneous value of reactive power" and "reactive power," (I.D).[6] The former varies with the time while the latter does not. In this respect the former corresponds to the instantaneous power input to a circuit, while the latter corresponds to the average or active power input.

If a sinusoidal potential is impressed on a series circuit of resistance $R$ and reactance $X$ the maximum value of instantaneous power input to the electric and magnetic fields equals the reactive power input as internationally defined. This fact may give rise to a prevalent belief that when a circuit is adjusted so that the reactive power (I.D.) input at the terminals is zero, *i.e.*, so that the terminal power factor is unity, the instantaneous value of the total reactive power is also zero, *i.e.*, the total stored energy in the electric and magnetic fields is constant. Unfortunately, however, this is not generally true in single-phase circuits except in one special case which we will presently describe. Neither is it true in polyphase circuits. If, for example, a symmetrical polyphase circuit has impressed upon it symmetrical potentials, the total instantaneous reactive power input is always zero, regardless of the power factor at which the circuit is operating. That is, the total stored energy is constant just as the total instantaneous power input to the circuit is constant.

Let us see what limitation must be imposed in the single-phase case for the belief to be true. Consider an $R$, $L$, $C$ network having two points of entry only, across which is impressed a sinusoidal electromotive force. Every inductance is assumed to have resistance associated with it, although the condensers may be assumed to be perfect.

Theorem: If this network is adjusted so that the total instantaneous power input to its electric and magnetic fields is zero, the currents in all of the branches of the network are in time phase.

Proof: The instantaneous power input to a resistance $R$ which is carrying a current

$$\sqrt{2}\,|\,I\,|\sin(\omega t + \alpha) \text{ is:}$$

$$p_R = R\,|\,I\,|^2 - R\,|\,I\,|^2 \cos 2\,(\omega t + \alpha)$$

If the same current flows through an inductance $L$ the instantaneous power input to the magnetic field is:

$$p_L = \omega L\,|\,I\,|^2 \sin 2\,(\omega t + \alpha)$$

If the current flows through a capacitance $C$, the instantaneous power input to the electric field is:

$$p_C = -\frac{1}{\omega C}\,|\,I\,|^2 \sin 2\,(\omega t + \alpha)$$

For the same reason that it is proper to represent this current by the rotating vector $I$ it is also proper to represent the double frequency portion of the power input to the resistance by the rotating vector $-jRI_R^2$ and the power input to the magnetic or electric field by the rotating vector $XI_X^2$, where $X$ is positive for inductance and negative for capacitance.[7] $I_R$ and $I_X$ are the rotating vectors which represent the currents in the resistance, $R$, and the reactance, $X$, respectively.

Therefore the double frequency portion of the power input at the terminals of the network may be represented by a rotating vector $S_0$ of the form

$$S_0 = \Sigma\,(-jRI_R^2 + XI_X^2) \qquad (7)$$

or

$$S_0 = -j\,\Sigma\,(RI_R^2 + jXI_X^2)$$

Compare this with equation (**4**).

The vector volt-ampere input at the terminals of the network is

$$P_0 + jQ_0 = \Sigma\,(R\,|\,I_R\,|^2 - jX\,|\,I_X\,|^2)$$

Note that while $S_0$ is obtained by a vector summation, $P_0$ is obtained by a numerical summation since $R$ is always positive and $Q_0$, by an algebraic summation since $X$ may be either positive (inductive) or negative (capacitive). Now it is well known that the amplitude of the double frequency power input equals the magnitude of the vector volt-amperes, that is:

$$|\,S_0\,| = \sqrt{P_0^2 + Q_0^2}$$

If the network is adjusted so that the total instantaneous power input to the magnetic and electric field is zero,

$$\Sigma\,XI_X^2 = 0$$

and

$$S_0 = -j\,\Sigma\,RI_R^2$$

Thus the magnitude of the vector sum $\Sigma\,RI_R^2$ equals the square root of the sum of the squares of the magnitudes of the numerical sum $\Sigma\,R\,|I_R\,|^2$ and of the algebraic sum $\Sigma\,X\,|\,I_X\,|^2$.

Since the vector sum of any number of vectors may be equal to but not greater than the numerical sum of their magnitudes, it follows that not only

$$|\,\Sigma\,RI_R^2\,| = \Sigma\,R\,|\,I_R\,|^2 \qquad (8)$$

but also

$$Q_0 = \Sigma\,X\,|\,I_X\,|^2 = 0$$

Therefore the reactive power $Q_0$ at the terminals is zero, and since the vector and numerical sums are equal, as shown by equation (**8**), the currents in all of the branches of the network which contain resistance are in time phase.

Since in the case we are considering the reactive power input, $Q_0$, at the terminals is zero, the input current, $I_0$, is in phase with the applied potential, $E_0$, and the network is equivalent[8] to resistance

$$\frac{E_0}{I_0} = R_0.$$

Thus the double frequency power input, $-jR_0I_0^2$, equals

---

[6] International definition.

[7] The square of a vector, $V$, is a vector, $V^2$, whose magnitude is the square of the magnitude of $V$ and whose phase angle is always double the phase angle of $V$. The speed of rotation of $V^2$ is thus twice the speed of rotation of $V$.

[8] In the steady state and at the given frequency.

$-j\sum RI_R^2$. From this it follows that all of the currents in the branches containing resistance are in phase with the input current at the points of entry.

It remains to consider those cases in which some of the branches of the network may not contain resistance. In any actual network every inductance would be associated with resistance, but it is often assumed that the capacitances are perfect, *i.e.*, without series resistance. Consider a network some of whose branches consist wholly of capacitance. When the currents flowing into any network and the impedances of its branches are known, the currents in all parts of the network are determined by applying the two Kirchhoff principles. Apply these principles to the capacitive portion of the network. The currents flowing into these capacitive branches will come either from branches containing resistance or directly from one or both of the points of entry. Since all of these input currents to the portion of the network under consideration are in time phase, and since all of the branches of this portion of the network have impedances of the form

$$-j\,\frac{1}{\omega C},$$

it follows that all of these capacitive currents will be in time phase with the input current. Thus the theorem is generally true for all actual networks.

We have therefore proved that if a single sinusoidal electromotive force is impressed on any actual $R$, $L$, $C$ network which is adjusted so that it operates at unity power factor the total instantaneous input to its electric and magnetic fields is zero only when the currents in all of the branches of the network are in time phase. Since such a network may be adjusted for unity power factor without having all of the currents in time phase it follows that there can be no general relation between the reactive power as defined by international agreement and the instantaneous value of the power input to the electric and magnetic fields.

Another interesting point is illustrated by the simple circuit shown in Fig. 1($a$). The resistance and reactance of the coil are equal and the reactances of the condensers are each one-half of the reactance of the coil. The vector diagram showing the potentials and currents is in Fig. 1($b$). From this are derived the vectors,

$$-\frac{1}{\omega C_1}I_{c1}^2,\ -\frac{1}{\omega C_2}I^2_{c2},\ \text{and}\ \omega L I_L^2$$

which represent the instantaneous reactive powers in the condensers and inductance. (See equation (**7**).) In this case the maximum value of the instantaneous reactive input at the terminals equals the reactive power (I.D.) input even though the currents are not in phase. Note, however, that the instantaneous reactive power input to $C_1$ is equal in magnitude, but in exact time opposition, to the instantaneous reactive power input to $C_2$; that is, it might reasonably be said that there is a direct interchange of energy between these condensers so as to maintain their total energy constant. Since the instantaneous reactive power input to the condensers is zero, the total instantaneous reactive input at the terminals equals that taken by the coil. From this point of view it would be reasonable to conclude that the reactive power input at the terminals is inductive, from which it would follow that the input current lags the applied potential. This is an entirely erroneous conclusion, since the input current leads the applied potential as is shown in the vector diagram.

We have attempted to obtain a physical conception of reactive power by associating it with the instantaneous power input to the electric and magnetic fields. We have clearly shown that the sum of the instantaneous values of reactive power in the different branches of a network may give no indication as to the value or character of the reactive power (I.D.) at the input terminals to the network.

Imagine the confusion of a student who is taught that sinusoidal electromotive forces or currents must be combined with due regard to their phase relations, while reactive powers, which he is also taught to think of as sinusoidal quantities, are combined without regard to their phase relations. In view of this it seems wise to discard this conception of reactive power entirely, at least when combining the reactive powers in a number of branches.

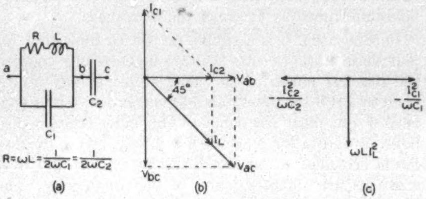

FIG. 1—SIMPLE CIRCUIT ($a$), POTENTIAL AND CURRENT VECTORS ($b$), AND VECTORS ($c$) WHICH REPRESENT THE INSTANTANEOUS REACTIVE POWER IN THE CONDENSERS AND INDUCTANCE

*II. Concept of Maximum Value of Stored Energy.* The reactive power might be associated with the maximum value of the stored energy. Consider two reactive coils connected in parallel. The total reactive power is the numerical sum of the reactive powers in the two branches, but the maximum values of the stored energy may occur at different times inasmuch as the currents may not be in time phase. Thus the maximum stored energy in the magnetic fields may not be equal to the sum of the maximum values of the stored energy in the individual fields. Thus this conception of reactive power is also open to the same objection as that we have already discussed.

*III. Concept of Average Stored Energy.* The reactive power might be associated with the average value of the stored energy, provided this stored energy is given a positive value when the current in the circuit leads the potential across the circuit, and is given a negative value when the current lags the potential difference. The very obvious advantage of using the mean value of the stored energy is that it has no phase relation associated with it, that is, if we do not regard plus and minus signs as indicating a phase relation. If a circuit contains a series inductance of constant value, $L$, and is carrying a sinusoidal current, $i = \sqrt{2}\,|\,I\,|\,\sin \omega t$, the instantaneous value of the stored energy is $\frac{1}{2} Li^2$. The mean value of this stored energy is $\frac{1}{2} L \left| I \right|^2$. Now the reactive power in this case is $Q = \omega L \left| I \right|^2$, that is, the reactive power is the mean value of the stored energy multiplied by $2\omega$. Exactly the same relation holds if the circuit contains capacitance and if the current is sinusoidal. We now have a physical conception of reactive power that holds for any single-phase static network, *i.e.*, having only two points of entry, in which all of the electromotive factors and currents are sinusoidal. That is, the reactive power at the terminals is the algebraic sum of the average values of the energy stored in the electric and magnetic fields multiplied by $4\pi$ times the frequency.

Furthermore, it is a simple matter to show that for polyphase static circuits that are magnetically coupled the reactive power is the mean stored energy multiplied by $2\omega$ if the potentials and currents are sinusoidal and of the same frequency. The same relation also holds for a rotating machine like a polyphase induction motor provided the potentials and currents in the stator windings are sinusoidal and of one frequency. The mean value of the stored magnetic energy, however, does not account for the reactive power input to a synchronous motor since the power factor at which the motor operates is controlled by the field excitation and may range from lagging to leading.

If a non-harmonic current, the effective values of whose harmonic components are $I_1$, $I_2$, and $I_3$, flows through a constant inductance $L$, the mean value of the stored energy is

$$\frac{1}{2} L \left(I_1^2 + I_2^2 + I_3^2\right).$$

If the definition for reactive power is extended to include harmonics as we have suggested the reactive power in this case is $\omega L \left(I_1^2 + 2I_2^2 + 3I_3^2\right)$. It thus bears no direct relation to the mean stored energy as it did with sinusoidal currents.

Finally, in all of those cases where, due to the presence of magnetic material, the inductance is a function of the current, it is not possible to determine the value of the mean stored magnetic energy inasmuch as the physical phenomena involved are not understood in any quantitative manner. Thus in these cases there is no determined relation between the reactive power and the mean stored energy.

If reactive power is measured by a meter of the dynamometer type in which the potential circuit consists wholly of inductance, the instrument is subject to frequency errors. Furthermore the instrument indicates the mean value of the stored magnetic energy if there are harmonics present and if the inductances in the network are independent of current strength. In fact, the definition of reactive power might be based on the meter reading. If this were done, however, the generalized mathematical concept of reactive power that has been here developed would have to be discarded.

*Conclusion.* Reactive power, as defined by international agreement, is fundamentally a mathematical quantity. At present it is based upon an assumption of sinusoidal potentials and currents. This limitation of a sinusoidal wave form can be removed and the definition will then correspond to that for active power. We would then have a truly scientific definition. If this were done the generality of the mathematical definition of reactive power and its use in circuit calculations would far outweigh any other consideration. Reactive power is due to some physical characteristic of the circuit which causes a phase displacement between the potential across the circuit and the current in it. Constant inductance and capacitance will produce this effect. It may also be produced by the electric arc or by resistance that varies with the current strength due to heating. In rotating synchronous machines the phase displacement can be controlled by the relative strength of the field poles. In general, however, reactive power cannot be said to equal any one definite physical quantity. The best physical concept that we have is based upon the mean value of the stored energy, but in determining this mean value the energy stored in an inductance must be counted of opposite sign to that stored in a condenser. Furthermore this concept is valid only when the circuit is linear and the impressed potentials are of a single frequency. Any concept based wholly upon the instantaneous value of the stored energy or of the time rate of change of the stored energy will probably lead to great confusion in the mind of the student. It is relatively unimportant that there is no general physical concept of reactive power. Were it defined as a physical quantity that did not prove useful in circuit analysis it would soon be forgotten.

It is important to note that for the purpose of circuit calculations the components of both the active and reactive power for *each* frequency need to be given. The *resultant* active and reactive power for all frequencies *combined* is of little value in circuit calculations.

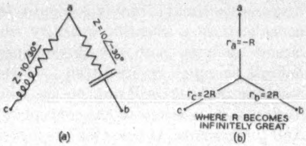
## POWER FACTOR

The general definition of the power factor of a single-phase network is the ratio of the power supplied, $P$, to the product of the applied potential difference, $V$, and the current, $I$. Under all conditions this product is the greatest power that the given effective current, $I$, can produce at the given potential difference, $V$. With this in mind the definition of power factor might be formulated as follows: Power factor is the ratio of the actual power to the greatest power that the given effective current and the given potential can produce. This form of the definition has one possible advantage. It can be extended to the general polyphase case where the applied potentials are not sinusoidal.

In the single-phase case the only load which in general will take the maximum amount of power for a given effective value of the current is a fixed non-reactive resistance. The accepted definition of power factor thus compares the actual load with a non-reactive resistance load, both of which take the same effective value of current at the same potential. When we attempt to obtain a corresponding conception of power factor in a polyphase circuit we must allow the resistances of the different phases of this non-reactive load to take on any value from plus to minus infinity. For example, take the simple three-phase load illustrated in Fig. 2($a$).

If the line potentials are sinusoidal and each has a value of 100 volts, the line currents are 20 amp, 10 amp, and 10 amp. In order to duplicate these line currents and have the branches non-reactive resistances they must have the values indicated in Fig. 2($b$). Although such a condition is physically impossible we may still consider the condition of maximum power for given values of effective currents. For example, the load shown in Fig. 2($a$) takes the greatest possible power for the given values of line currents. The reactive power input to this load is zero.

Fig. 2—Simple Three-Phase Load ($a$), and Non-Reactive Resistances ($b$) Giving the Same Line Current



In the following discussion we shall assume that the currents and potentials are sinusoidal and of the same frequency. First consider a network that has three points of entry. This might be either a three-phase circuit or a three-wire two-phase circuit. The potentials between the successive line conductors are fixed. This determines a triangle of the line potential vectors. Similarly, since the magnitudes of the line currents are also known—by hypothesis—the current vectors also determine a triangle. This triangle may take one of two forms determined by whether the currents are in the same phase order as the line potentials or in the opposite phase order. In either case the maximum value of the power supplied equals the magnitude of the vector volt-amperes, $\sqrt{P^2 + Q^2}$ but the vector volt-amperes are greater when the phase order of the currents is the same as that of the potentials. Thus, in this case of a three-wire circuit, the maximum value of the power that can be supplied by the given potential and currents equals the vector volt-amperes determined on the assumption that the phase orders of the potentials and currents are the same. If it happens that the phase orders of the line currents and line potentials are opposite, the magnitude of the vector volt-amperes, *viz.*, $\sqrt{P_0^2 + Q_0^2}$, is less than the maximum possible power for the given system of line potentials and of line currents. This condition may arise when an induction motor is running idly on an unbalanced potential system. All that is necessary is to have an unbalance in the line potentials greater than the ratio of the no-load admittance to the blocked admittance of the motor. The negative-sequence current will then be greater than the positive-sequence current and the phase order of the line currents will be opposite to the phase order of the line potentials. There is thus the possibility that the power factor as determined by the ratio of the actual power to the maximum power for the given line potentials and line currents will not equal the power factor as determined by the ratio of the actual power to the magnitude of the vector volt-amperes.

Let us now consider a network into which currents flow at four or more points; for example, a three-phase circuit with neutral connection, or a four-phase circuit. The line potentials are fixed both in magnitude and in relative phase. Assume for the moment that the phase relations of the line currents are fixed with respect to each other but not with respect to the line potentials. Then, if the phase order of the line currents is the same as that of the line potentials, the maximum power for this particular current polygon is equal to the magnitude of the total vector volt-amperes, *viz.*, $\sqrt{P_0^2 + Q_0^2}$. With four or more currents the phase relations of the currents with respect to each other are not fixed by the magnitudes of the currents as they are in a network having three points of entry. The magnitude of the vector volt-amperes, however, depends upon the phase relations of the currents with respect to one another, and there is one particular current vector polygon for which the vector volt-amperes are greater than for any other. Thus the magnitude of the total vector volt-amperes, *viz.*, $\sqrt{P_0^2 + Q_0^2}$ is generally less than the maximum power that can be developed by the given system of line potentials and the given line currents. For example, consider a symmetrical four-phase circuit having line potentials of 100 volts between adjacent conductors and 141.4 volts between alternate conductors. Connect two resistance loads, each of 10 ohms, across opposite pairs of line conductors. The line currents are each 10 amp. The active power is 2,000 watts and the reactive power is zero. The 2,000 watts is the maximum power for this particular current polygon. Now connect four resistances, each of 14.14 ohms across adjacent pairs of line conductors. The line currents are again 10 amp. The reactive power is again zero, but the active power is now 2,828 watts.

The 2,828 watts is not only the maximum power for this current polygon but it is the greatest power that can be developed by any load whose line currents are each 10 amp. If power factor should be defined as the ratio of the actual power to the maximum power that can be developed for the given ampere values of the line currents, the power factor of the first resistance load would be 0.707. This power factor would be the power factor of the load considered from a polyphase standpoint. Considered from the point of view of individual single-phase loads, the power factors are each unity. The first of these loads is unbalanced, and it is probably better to use two factors in describing it, *viz.*, power factor based upon active and reactive power, and unbalance factor based upon symmetrical components. Thus it seems unwise to extend to polyphase circuits the conception of single-phase power factor, that is, that it is the ratio of the actual power to the maximum power for the given potential and current.

## CONCLUSION

We have given definitions for potential, current, and active and reactive power which are independent of wave form and of circuit conditions. In order to use these quantities in circuit analysis when there are harmonics present, it is necessary to know their individual harmonic components. The value of the total or resultant quantity is not sufficient. By definition, single-phase power factor is a blanket factor which covers and so disregards any deviation in wave form from the sinusoidal. Thus it is not a quantity that can be used in circuit analysis when there are harmonics present. If polyphase power factor is defined as the ratio of the power to the magnitude of the vector volt-amperes it is likewise a useless quantity in circuit analysis if there are harmonics present. Furthermore, this definition of polyphase power factor makes it a derived quantity which depends upon the active and reactive power. Even when there are no harmonics present so that power factor may be legitimately used, the circuit calculations are usually simpler if the loads are determined by their active and reactive powers rather than by their power factors. That is, as far as circuit analysis is concerned, power factor is a quantity whose retirement need scarcely be noted.

There is, however, another and important use for power factor. There is a need for just such a blanket factor when specifying the character of power loads from a commercial standpoint, that is, when writing specifications or power rates. In that case it does not seem necessary that power factor should have a rigorous scientific definition such as has been given potential, current, and power, and can be given reactive power. In these quantities we have adequate means for specifying our circuits for the purpose of analysis. On the other hand, it seems best to consider power factor as a purely commercial quantity and to define it accordingly. It may be that the present definitions of single-phase and polyphase power factor are adequate. However, before the definition is written we should decide upon the status of power factor; whether it is to be classed as a scientific quantity like power, for example, or as a commercial quantity like load factor. In making this decision we should frankly recognize that if it is to be considered as a scientific quantity which is useful in circuit analysis, both the single-phase and polyphase definitions must be rewritten. If this is done, the resulting quantity will not, on the whole, be as useful in circuit calculations as the concept of reactive power. And furthermore, in this case the power factor will not be the useful commercial quantity which now appears in specifications and power contracts.

## Discussion

For discussion of this paper see page 779.

# Notes on the Measurement of Reactive Volt-Amperes

BY W. H. PRATT*

Fellow, A.I.E.E.

***Synopsis.***—*In the following paper, the character of the quantity known as reactive volt-amperes is first discussed and its dependence on the assumption of a definite type of periodicity is brought out, this in contrast to certain other a-c quantities. It is pointed out that on account of the rather complicated relation that it bears to the flow of energy in an electric circuit serious difficulties are met in its measurement except in the simpler conditions of balanced voltages, in a polyphase circuit, and sinusoidal waves. Two procedures are outlined which though they are not premised on balanced voltages have frequency and wave form limitations.*

*In the latter part of the paper, the relation of the quantity of energy that surges in an a-c circuit in which there is energy storage, to the average flow of energy is considered, and advantages of this conception as a basis for rates are indicated.*

*Finally, it is pointed out that reactive volt-amperes is of the nature of a complementary quantity rather than a specific activity of the electric circuit which when suitably combined with power gives volt-amperes.*

* * * * *

CERTAIN of the quantities used to describe the phenomena associated with alternating currents require the postulation of a definite type of periodicity or a definite frequency in order to give them meaning. Among these are phase angle and reactive volt-amperes. Even with an almost haphazard character of oscillation, an alternating current may have a definite root-mean-square value provided the averaging is carried over a sufficient interval, but in stating a value of reactive volt-amperes, a definitely ordered frequency must be assumed.

In the measurement of reactive volt-amperes or reactive volt-ampere-hours, we are concerned with quantities the definitions of which are dependent on the assumption of periodicity and which consequently can have definite values only when considered over intervals long enough to establish a definite character to that periodicity. In the ordinary case in which the frequency is constant and the measured quantities and their components show simple sinusoidal variation, the procedure for measurement need not be very complicated though the extreme simplicity of power measurement apparently cannot be attained. Most commercial devices for the measurement of reactive volt-amperes are designed on the assumption that the complications arising from a complexity in wave form may be neglected.

If the problem at hand happens to be to measure a particular type of quantity, it is useful to know something more about that quantity than the equation that defines it. The equation may be the residue remaining after numerous terms, that must be represented in the mechanism for measurement, have been eliminated.

In the measurement of energy with the ordinary watthour meter, we integrate, with respect to time, the instantaneous products of current and voltage. In the measurement of power, using the ordinary wattmeter, we progressively average values that are obtained by integration. In the former, the integration is continued indefinitely; in the latter, the integration and averaging occur by reason of the inertia of the deflecting member of the instrument. In both measurements, we are dealing from instant to instant with components of power, *i.e.*, instantaneous current and instantaneous voltage that are readily accessible in the electrical circuit; the measured quantities have a meaning however short the chosen interval.

In a single phase electric circuit containing inductance or capacity, in each half cycle there is a storage and release of energy which is determined by the changing instantaneous values of current and voltage. An oscillographic wattmeter shows this as an ebb and flow of power in the circuit. In a balanced polyphase circuit considered as a whole, the flow of energy may be at a perfectly uniform rate because the storage of energy in one part of the circuit is exactly balanced by the release of energy in another part; yet each conductor is the scene of a pulsation of energy.

Assume sinusoidal voltage and current according to equations (**1**) and (**2**). Their product gives the power equation (**3**) which transformed, shows this product to be equivalent to the sum of two terms, equations (**4**) and (**5**). One term is an average value of the power and so independent of time. The second is a double frequency pulsation of power of which the average value over an integral number of half cycles is zero and which consequently closely approximates zero over any sufficiently long interval of time.

If the time origin be so chosen that it falls exactly midway between the time of zero value of voltage and the time of zero value of current, the very simple form shown in equation (**9**) results.

Instead of expressing the relation of the sinusoidal pulsation of power to the time origin as an angle, we may show this pulsation as the sum of two sinusoidal components, one passing through maximum, the other through zero value at time zero (equation (**6**) ). If also, we chose zero time to coincide with the time of zero value of either voltage or current, equations (**7**) and (**8**) result. These have the peculiarity that the coefficient

EQUATIONS 1 TO 9

$$e = E_m \sin(\omega t - \varphi_e) \tag{1}$$

$$i = I_m \sin(\omega t - \varphi_i) \tag{2}$$

$$p = ei = E_m I_m \sin(\omega t - \varphi_e)\sin(\omega t - \varphi_i) \tag{3}$$

$$= \frac{E_m I_m}{2}\cos(\varphi_i - \varphi_e) - \frac{E_m I_m}{2}\cos(2\omega t - \varphi_e - \varphi_i) \tag{4}$$

Let $\varphi = \varphi_i - \varphi_e$

$$p = \frac{E_m I_m}{2}\cos\varphi - \frac{E_m I_m}{2}\cos(2\omega t - [\varphi_e + \varphi_i]) \tag{5}$$

$$= \frac{E_m I_m}{2}\cos\varphi - \frac{E_m I_m}{2}[\cos(\varphi_e + \varphi_i)\cos 2\omega t + \sin(\varphi_e + \varphi_i)\sin 2\omega t] \tag{6}$$

If $\varphi_e = 0$

$$p = \frac{E_m I_m}{2}\cos\varphi - \frac{E_m I_m}{2}(\cos\varphi\cos 2\omega t + \sin\varphi\sin 2\omega t) \tag{7}$$

Is $\varphi_i = 0$

$$p = \frac{E_m I_m}{2}\cos\varphi - \frac{E_m I_m}{2}(\cos\varphi\cos 2\omega t - \sin\varphi\sin 2\omega t) \tag{8}$$

From equation (5) if $\varphi_e = -\varphi_i$

$$p = \frac{E_m I_m}{2}\cos\varphi - \frac{E_m I_m}{2}\cos 2\omega t \tag{9}$$

$$= EI(\cos\varphi - \cos 2\omega t) \tag{9a}$$

of the cosine term of power pulsation is the same as the first term of the equation, *i.e.*, the value of average power. As is also true in equation (6), the sum of the square of the coefficient of the double frequency sine term and the square of the coefficient of the double frequency cosine term is $(E_m^2 I_m^2)/4$ or in rms quantities $E^2I^2$.

As indicated by these several equations, the content of the components that are due to the pulsation of energy is dependent on the choice of time origin. It is only when the time origin happens to coincide with the time when either the current or voltage wave passes through zero value that the terms in the power equation correspond to, and entirely separate, energy dissipation and energy surging; but the first term always gives average power.

When the current and voltage waves contain harmonics, the average power is the sum of the averages of the power contributed by the harmonics individually, *i.e.*, in the average power, there are no terms due to the product of components of different frequency although such products must occur in the equation for the instantaneous power. So, if we would express the surging of energy due to the harmonics separately, we must in general choose a different time origin for each harmonic. Otherwise, pulsation of power that corresponds to dissipated energy can no longer be separated from the pulsation due to energy stored.

In equations (7) and (8), $\frac{1}{2}E_m I_m \cos\varphi$ and $\frac{1}{2}E_m I_m \sin\varphi$ are coordinate insofar as they are the coefficients of two arbitrarily chosen components of the pulsation of power. On the other hand, $\frac{1}{2}E_m I_m \cos\varphi$ as a measure of the average value of power has no corresponding term in $\sin\varphi$ in the power equation.

We may assume a quantity $\frac{1}{2}E_m I_m \sin\varphi$ analogous to $\frac{1}{2}E_m I_m \cos\varphi$. This is a quantity such that its square when added to the square of the average power gives a quantity in $E_m$ and $I_m$ independent of the phase angle $\varphi$. In rms quantities, we have $(E^2I^2\cos^2\varphi + E^2I^2\sin^2\varphi)^{1/2} = EI$.

Using now rms quantities, $EI\cos\varphi$ has a real existence in the circuit in that it can manifest itself as a measure of the reaction between simultaneously occurring fields, the one due to the current in the circuit and the other produced by a current proportional to the electromotive force.

In contrast, $EI\sin\varphi$ may be looked upon as involving the concept of memory or prediction, *i.e.*, memory + or − depending on the viewpoint.* To be more specific: $EI\sin\varphi$ is the average value of products of instantaneous values of current each multiplied by that value of voltage that existed in the circuit 1/4 cycle earlier. In a 60-cycle circuit, each instantaneous current value must be multiplied by the value of voltage that existed 1/240 sec earlier. If the current and voltage waves contain harmonics, each harmonic must be considered separately, *i.e.*, the instantaneous values of fundamental frequency current must be multiplied by the value of fundamental frequency voltage that existed 1/4 cycle earlier. Each instantaneous value of third harmonic current must be multiplied by the value of third harmonic voltage that occurred 1/12 of a fundamental cycle earlier, etc. In a 60-cycle circuit containing fifth and seventh harmonics, products of pairs of quantities separated in time by intervals of 1/240, 1/1,200, and 1/1,680 sec, respectively, must be secured. Herein doubtless lies the practical difficulty of realizing a theoretically correct procedure in the measurement of reactive volt-amperes or reactive volt-ampere-hours, for mechanisms that in effect have discriminating memories, or something equivalent must be arranged to multiply, sum, and average quantities that have no simultaneous existence.

---

*It is very desirable that a convention in regard to sign should be adopted. It is convenient usually to assume inductive reactive volt-ampere to be negative. Reasons for this convention, discussed from the geometrical viewpoint, are briefly given in Appendix II.

It may be pointed out that each instantaneous product that goes to determine $EI \sin \varphi$ is related simply by the numerical ratio $\tan \varphi$ with the corresponding element which determines $EI \cos \varphi$. However, $\varphi$ cannot have a valid meaning unless intervals of time sufficient to establish a definite periodicity can be taken into account which brings us again to the history, *i.e.*, memory of what has been happening in the circuit.

In contrast, $p = ei$ is the instantaneous value of the power whatever functions of time may represent $e$ and $i$. In a-c measurements, we are most frequently interested in average power, *i.e.*, power averaged over an integral number of half cycles or over a time so long that the variation of power within a single half cycle may be neglected.

The relation $\frac{d}{d\varphi} \cos \varphi = - \sin \varphi$ suggests a possible approach, but the quantities, current and voltage, are sine functions of time and therefore their derivatives with respect to time (which could easily be made use of in a measuring device) are proportional to frequency, while $EI \sin \varphi$ is independent of frequency. Indeed if the frequency can be assumed to be constant and the current or voltage wave simply sinusoidal, we may use the derivative of the voltage (represented by the current flowing in a highly inductive derived [capacitive] circuit) to excite the potential circuit of an otherwise, standard wattmeter, and thereby secure a measurement of reactive volt-amperes. Harmonics, however, are represented in the reading of such an instrument as 3, 5, 7, etc., times their real contribution, or if inductive reactance be used, but 1/3, 1/5, 1/7, etc., of their proper values appear.

In a symmetrical polyphase circuit where the voltages or currents are simple sinusoidal functions of the time, the simplest way to get a cosine function voltage for the measurement of reactive volt-amperes, to replace the sine function voltage used in the measurement of power, is by cross connections or cross transformations of the polyphase voltages.

If the voltages are not symmetrical or at least if they do not maintain permanently an exact relation, properly displaced currents to represent the desired voltages may be obtained by the use of resistances together with capacitances as principal components of the voltage circuits of induction meters or by the use of reactive coils in the voltage circuits of electrodynamic types of meters or indicating instruments. This arrangement is equally applicable to single phase circuits and has the advantage that for a definite frequency the potential circuit current is entirely independent of any variations that may occur in the relations of voltage or phase of the polyphase circuit as a whole. It has the disadvantage that currents flowing in these circuits instead of varying inversely with the frequency as they should in the induction meter, or of remaining independent of frequency as they should in the electrodynamic types of apparatus, follow laws which cause errors proportional to the changes of frequency to appear. The corresponding energy and power meters give readings only slightly, or practically not at all, influenced by change of frequency.

When only small changes of frequency are involved, it is possible to effect almost perfect frequency compensation by using capacitive and inductive circuits in parallel, but if irregularities of wave form are present, serious errors may be made to appear by frequency compensations of this general type.

Another procedure that has much to recommend it is to introduce phase displacements in both current and voltage circuits; for instance, a 45-deg advance in the one and a 45-deg retardation in the other. To do this successfully requires great care in design for, in general, current circuits must be suitable for wide ranges of current; this requires that any reactances used in the current circuits shall have characteristics almost wholly uninfluenced by any iron that may be used.

In the discussion that has been given so far, the difficulties connected with irregular wave forms have been mentioned only incidentally. It is probably true that the occurrence of large errors in the measurement of reactive volt-amperes or reactive volt-ampere-hours by reason of complex wave form is infrequent. This is because the simultaneous occurrence of greatly distorted current and voltage waves is unusual.

If we are dealing with a polyphase circuit and make use of cross-phase connections to secure the displaced phase of voltage for reactive measurement, we find this condition: Assuming the voltage source so chosen that the fundamental is 90 deg behind that of the corresponding voltage used for power measurement, the third harmonic voltage will be displaced 3 x 90 deg backward, which is equivalent to 90 deg ahead, the 5th 90 deg behind, the 7th 90 deg ahead and so on. If there is any reactive volt-ampereage due to these harmonics, the amount due to the 5th, 9th, etc., will be properly added, while that due to the 3rd, 7th, 11th, etc., will be subtracted when it should be added.

If a 10 per cent seventh harmonic voltage were accompanied by a 90-deg displaced current of 5 per cent, the incorrect sign that would be given to the seventh harmonic contribution in the reactive volt-amperes would result in a 1 per cent error. But a 10 per cent harmonic in voltage is not met in modern generators. Even a large harmonic of current unless accompanied by an appreciable voltage of the same frequency contributes nothing to either the average power or to polyphase reactive volt-amperes, although they do contribute to the volt-amperes as measured in single-phase circuits.

If the voltages of the polyphase circuit are unbalanced or if we are concerned with single-phase measurement, the cross-phase arrangement for securing displaced phase excitation for the voltage circuits of meters or instruments is unsuitable or impossible. If the frequency is constant, recourse may be had to the use of altered potential circuits as already discussed. The substitution of resistances, or resistances and capacities, for reactances in the potential circuits of induction meters tends to exaggerate the contribution of the harmonics; the substitution of reactance for resistance in the potential circuit of an indicating instrument tends to minimize their effect. The reasons may readily be seen: In the induction meter the voltage circuit excitation should vary inversely as the frequency so that the eddy current strength may remain independent of frequency, but with the equivalent of a non-inductive circuit, the current in such a potential circuit will be independent of frequency and a seventh harmonic eddy current, for instance, would be seven times too large. If, however, the seventh harmonic of current is small, the error might be unimportant.

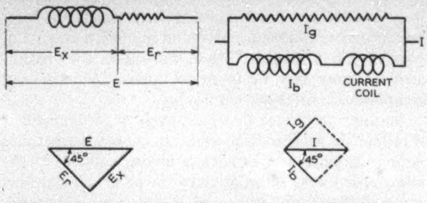

Fig. 1—Circuits of One Form of Reactive Volt-Ampere-Hour Meter and Associated Vector Relations at Frequency *N*

In the indicating instrument with an inductive potential circuit, components due to the harmonics become proportionately too small, *i.e.*, instead of being independent of the frequency, they are inversely proportional thereto.

It is possible to imagine branched circuits, each branch resonant to a particular harmonic, the whole proportioned to give substantially correct current values for each of the harmonics at a chosen frequency, but the phase relations would be completely unstable and so the arrangement appears unusable.

If the potential circuit of an induction meter is made up of non-inductive resistance in series with the customary inductive resistance and the current circuit, supplemented with additional inductance if necessary, is shunted by a non-inductive resistance, (Figs. 1 and 2) the various values of these circuit elements may be so chosen that the difference between the displacements of the currents in the potential and current circuits becomes zero instead of the customary 90 deg. This relation if true for any selected frequency is true for all frequencies when the inductive branch is pure inductance.

If at fundamental frequency, the displacement of the currents which represent voltage and current are each 45 deg from the voltage and current respectively, the harmonic components of the reactive volt-amperes will be recorded in the ratio $\dfrac{1}{n+\dfrac{1}{n}}$ to their proper value where $n$ is the order of the harmonic, *i.e.*, they will be greatly underrecorded. If, however, the 45 deg relation is made to hold at double normal frequency or at triple frequency, the harmonics will be recorded in ratio to correct values as follows:

| Harmonic | 1 | 3 | 5 | 7 | 9 | 11 | 13 |
|---|---|---|---|---|---|---|---|
| 45° adjustment at double frequency | 1 | 1.13 | 0.86 | 0.66 | 0.53 | 0.44 | 0.33 |
| 45° adjustment at triple frequency | 1 | 2.50 | 1.47 | 1.21 | 1.00 | 0.85 | 0.73 |

If low frequency harmonics are prominent, the double frequency adjustment may well be chosen. If harmonics of consequence in the range 7th to 13th are present, the triple frequency adjustment should be considered. Circuit arrangements just discussed involve losses in the meter much higher than those in the ordinary forms of induction meter, yet there are probably conditions where they would be advantageous.

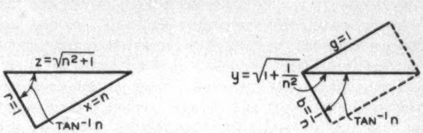

Fig. 2—Impedance of Potential Circuit (Left) and Admittance of Current Circuit (Right) of the Meter of Fig. 1, at Frequency *nN* Relative to Values at Frequency *N*

At frequency *nN*

$$\text{Current in potential circuit} = k_1 \frac{E}{\sqrt{n^2+1}}$$

$$\text{Current in current circuit} = k_2 \frac{1}{n} \cdot \frac{I}{\sqrt{1+\frac{1}{n^2}}}$$

$$\text{Product} = kEI \frac{1}{\sqrt{n^2+1}} \cdot \frac{1}{\sqrt{n^2+1}} = kEI \frac{1}{n^2+1}$$

$$= kEI \cdot \frac{1}{n} \cdot \frac{1}{n+\frac{1}{n}}$$

The general absence of important harmonics in the voltage waves of commercial circuits, the approximate balance of their voltages, and the very great convenience of making use of regularly listed types of meters dictates the choice of regular watthour meters to be connected in circuit with suitable transformers for cross-phase connection for securing 90-deg phase displacement, as the most practical means of measuring reactive kva except in exceptional circumstances.

In the measurement of energy in a three-phase or analogous circuits using double-element meters, when the power factor is low, we encounter the condition of two relatively large torques opposing each other in the meter so that the balance between meter elements becomes of great importance. Similarly, in reactive measurement when the power factor is high, balance of elements is of primary importance. Three-element meters do not suffer from such limitations.

A form of measurement in which a composite quantity is secured, namely, $a \times$ watts $+ b \times$ reactive volt-amperes can be effected by exciting the potential circuit of a wattmeter at a phase intermediate between that of the voltage and 90 deg therefrom. The phase once chosen and established by the proportion of resistance to reactance in the potential circuit, or otherwise, fixes the ratio of $a$ to $b$. The readings of the instrument are then $a \times$ watts $+ b \times$ reactive volt-amperes, and this remains true irrespective of the power factor. Meters, similar to watthour meters, in which this quantity is integrated with respect to time have found considerable use on this continent.

Analysis of alternating-current phenomena is almost wholly built upon the ideas that a fairly equivalent representation of what occurs can be had by considering current, voltage, and power as simple sinusoidal quantities with reference to time and that average rms values of these quantities are almost fundamental entities, at least in ordinary technical discussions. These ideas have lead to the conceptions of "apparent power," "reactive voltamperes," and "power factor," all of which, but especially the last, have so enmeshed themselves in general and specific discussions of technical and practical alternating current problems that, at least in the author's opinion, the true significance of some of these more or less unreal quantities has become obscured; conceptions of reality have been built up around them that are the result of a free and easy use of terms that suggest and help to evaluate but very indirectly indicate what occurs. It is even possible that this has gone so far that fundamentally incorrect ideas actually are distorting technical understanding and diverting effort into wrong channels. The author has the impression that reactive volt-amperage generally is regarded as a measure of the surging of energy in an alternating current circuit. The relation to the latter will be discussed further.

The flow of power in an electric circuit may present itself in various ways depending on the character of the circuit. The flow may be continuously in one direction and at a constant rate as in a steadily loaded d-c circuit; it may be continuously in one direction but pulsating as in the case of a circuit having a non-uniform, unidirectional voltage of any form provided there is no storage of energy; it may have a constant average value when averaged over a sufficient interval of time as in the case of a steady alternating current; or it may be entirely irregular.

Whenever the circuit contains inductance or capacitance, with every change of current or voltage there is a change in the amount of energy stored in the system so that superposed on a more or less steady principal flow of energy there may be a surging of energy due to the increase and decrease of magnetic and of electric energy in the system. When the change of voltage is definitely periodic, this surging can be signalized as reactive volt-amperes and reactive volt-ampere-hours.

With zero time chosen at random and with no other knowledge of the circuit than that given by the measuring devices at the supply end, there can be no distinction between energy stored in the circuit and energy transferred outside except when the voltage is definitely periodic. For example, at the supply end of a d-c circuit, no distinction can be made between energy used to build up a magnetic field and energy consumed in the same interval to supply $I^2R$ losses.

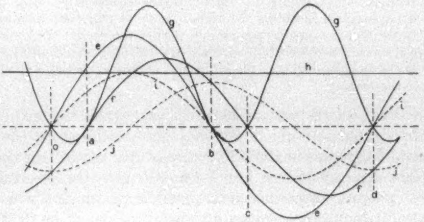

FIG. 3—SINE-WAVE VOLTAGE, CURRENT, AND POWER CURVES WITH CURRENT LAGGING 40 DEG BEHIND THE VOLTAGE

*a-b-c-d* represents times of power reversal

$a$ corresponds to $\frac{\varphi}{\omega}$ in equation (13)

$b$ corresponds to $\frac{1}{2N}$ in equation (13)

| | | | |
|---|---|---|---|
| *e-e* | voltage wave | *h* | average power |
| *f-f* | current wave | *i-i* | active component of current |
| *g-g* | power wave | *j-j* | reactive component of current |

In a single-phase a-c circuit or in each conductor of a polyphase a-c circuit, whenever there is storage of energy, the pulsation of power includes the reversal of the direction of flow of energy. This is a phenomenon that lends itself to exact and simple definition, for the quantities involved are the simultaneously occurring elements of current and voltage. No special interpretation of the significance of harmonic inclusions is required, for no assumption in regard to the type of periodicity need be made.

If we rewrite equation (7) in the form

$$p = \frac{E_m I_m}{2} \cos \varphi \, (1 - \cos 2\omega t) + \frac{E_m I_m}{2} \sin \varphi \sin 2\omega t \tag{10}$$

we observe that that portion of the power of which the coefficient is $(E_m I_m/2)\sin\varphi$ can have negative as well as positive values. The last term is positive during each alternate one-fourth cycle and negative during the other one-fourth cycles. However, taken by itself, this term gives no idea of the positive and negative flow of energy in the circuit except for the two limiting conditions, when $\varphi$ is either 0 or $\pi/2$. At intermediate values, the pulsation of positive power must be considered if we would evaluate separately the positive and negative flow of energy.

At this point will be introduced a quotation from U.S. Patent No. 1,657,262 to Karapetoff, for which the application was filed Oct. 5, 1923:

> "It is the primary object of my invention to provide a metering scheme for low power factor loads which will be more readily understood by the average consumer and is based upon the assumption that any consumer whose installation causes out-of-phase current in the line is, in fact, a periodic borrower of electric energy. During a part of the cycle he takes more energy than he needs, stores the excess in various magnetic fluxes in his apparatus, assuming the current to be lagging, and then returns it to the line during another part of the cycle. He is like a restaurant keeper who buys, say, one hundred pounds of meat in the morning and asks the butcher to take back twenty pounds in the evening."

In the early part of 1931, or just earlier, the author had tabulated much material corresponding to that which appears in the latter part of this paper. In the late summer of that year he had in view the securing of patents on certain instrument arrangements when the patent just mentioned (which was issued in 1928) was brought to his attention; thereupon further work on a proposed paper was discontinued. To round out this general discussion, the following observations seem to be in order.

If an electrodynamic wattmeter is connected to an a-c circuit with a half wave rectifier in series with its potential circuit, another in series with its current circuit, and a third connected in reverse polarity around the current circuit of the instrument to insure continuity in the circuit as a whole, torque will be developed in the instrument only during those periods in which current flows simultaneously in both of the instrument windings. Four situations are possibly to only one of which the instrument so connected will respond. A condition corresponding to each situation will occur at least once in every cycle as follows:

| | Voltage | Current | Power |
|---|---|---|---|
| 1. | + | + | + |
| 2. | + | − | − |
| 3. | − | − | + |
| 4. | − | + | − |

If now, four electrodynamic instrument elements are connected in the single phase a-c circuit through rectifiers as just indicated, each of the four power quantities may be measured separately. If the voltage and current waves are symmetrical, no interest would attach to a separation of (**1**) and (**3**), or (**2**) and (**4**), so (**1**) and (**3**) may be combined as a two-element electrodynamic instrument and similarly (**2**) and (**4**). Furthermore, with symmetrical waves, the energy flow corresponding to (**1**) would equal the energy flow corresponding to (**3**) so a single element could suffice for measuring positive flow and a single element for measuring negative flow; that is, by multiplying by two the reading of one element, and discarding the other.

Moreover, the algebraic sum of the indications of the four elements averaged over an integral number of half cycles would give the same quantity as the reading of an ordinary indicating wattmeter, *i.e.*, the arithmetical difference between the positive and negative flow, so an indicating wattmeter connected in the ordinary manner supplemented by another instrument connected to indicate as per (**2**) or (**4**) would give all the information necessary to evaluate average positive power, average power, and average negative power. Reactive volt-amperes, volt-amperes, and power factor could be calculated from these readings if the power factor is constant and if the flow is sinusoidal. If the wave forms are complex, a self-defining relation between positive and negative flow of energy results.

The distribution of energy flow in the several divisions can be obtained by integrating the power equation with respect to time between limits determined by the epochs corresponding to the reversals of voltage and current. This will be illustrated in its relation to sinusoidal waves.

$$p = EI\cos\varphi - EI\cos\varphi\cos 2\omega t - EI\sin\varphi\sin 2\omega t \qquad (\mathbf{11})$$

$$W = \int p\,dt = EI\cos\varphi\cdot t - \frac{1}{2\omega}EI\cos\varphi\sin 2\omega t + \frac{1}{2\omega}EI\sin\varphi\cos 2\,\omega t \qquad (\mathbf{12})$$

$$W_1 = [W]_{\frac{\varphi}{\omega}}^{\frac{1}{2N}} = \frac{1}{2N}EI\cos\varphi - \frac{\varphi}{\omega}EI\cos\varphi - \frac{1}{2\omega}EI\cos\varphi\sin 2\pi + \frac{1}{2\omega}EI\cos\varphi\sin 2\varphi + \frac{1}{2\omega}EI\sin\varphi\cos 2\pi - \frac{1}{2\omega}EI\sin\varphi\cos 2\varphi \qquad (\mathbf{13})$$

$$= \frac{1}{2N}EI\cos\varphi - \frac{\varphi}{\omega}EI\cos\varphi + \frac{1}{2\omega}EI\sin\varphi + \frac{1}{2\omega}EI\sin\varphi \qquad (\mathbf{13a})$$

$$= \frac{1}{2N}EI\cos\varphi - \frac{\varphi}{\omega}EI\cos\varphi + \frac{1}{\omega}EI\sin\varphi \qquad (\mathbf{13b})$$

$$W_1 + W_3 = \frac{1}{N} EI\cos\varphi - \frac{2\varphi}{\omega} EI\cos\varphi + \frac{2}{\omega} EI\sin\varphi \quad (14)$$

$$\frac{W_1 + W_3}{\dfrac{1}{N}} = EI\cos\varphi - \frac{\varphi}{\pi} EI\cos\varphi + \frac{1}{\pi} EI\sin\varphi \quad (15)$$

$$= EI\left[\cos\varphi + \frac{1}{\pi}(\sin\varphi - \varphi\cos\varphi)\right] \quad (15a)$$

$$W_2 = [W]_0^{\frac{\varphi}{\omega}} = \frac{\varphi}{\omega} EI\cos\varphi - \frac{1}{2\omega} EI\cos\varphi\sin 2\varphi + \frac{1}{2\omega} EI\sin\varphi\cos 2\varphi - \frac{1}{2\omega} EI\sin\varphi$$

$$= \frac{\varphi}{\omega} EI\cos\varphi - \frac{1}{2\omega} EI\sin\varphi - \frac{1}{2\omega} EI\sin\varphi \quad (16)$$

$$\frac{W_2 + W_4}{\dfrac{1}{N}} = \frac{\varphi}{\pi} EI\cos\varphi - \frac{1}{\pi} EI\sin\varphi$$

$$= EI \cdot \frac{1}{\pi}(\varphi\cos\varphi - \sin\varphi) \quad (17)$$

$$\text{Average power} = \frac{W_1 + W_2 + W_3 + W_4}{\dfrac{1}{N}} = EI\cos\varphi \quad (18)$$

$$\frac{\text{Average negative power}}{\text{Average positive power}} = \frac{\varphi\cos\varphi - \sin\varphi}{\pi\cos\varphi - \varphi\cos\varphi + \sin\varphi} = \frac{\varphi - \tan\varphi}{\pi - \varphi + \tan\varphi} \quad (19)$$

Average positive power = average power − average negative power

Reactive volt-amperes $= EI\sin\varphi$

$$\text{Average negative power} = \frac{1}{\pi} EI(\varphi\cos\varphi - \sin\varphi)$$

$$= \frac{\varphi}{\pi}\text{ average power} - \frac{1}{\pi}\text{ reactive volt-amperes}$$

$$= \frac{1}{\pi}(\varphi\text{ average power} - \text{reactive volt-amperes})$$

$$\text{Average positive power} = \left(1 - \frac{\varphi}{\pi}\right)\text{ average power} + \frac{1}{\pi}\text{ reactive volt-amperes}$$

$$= \frac{1}{\pi}[(\pi - \varphi)\text{ average power} + \text{reactive volt-amperes}]$$

TABLE I

| 90° | 1.000 | 0.000 | 0.000 | 1.000 | 0.318 | 0.318 |

Column 2 gives reactive factor. Column 3 gives power factor.
Column 6 gives ratio of average negative power to volt-amperes.
Colmun 7 gives ratio of average positive power to volt-amperes.

Table I gives a good idea of the relative magnitudes of the quantities under discussion. It is suggested that average positive power (column 7) could very well form the basis for rate schedules. It would introduce substantially no penalty for power factor for values of the latter above 90 per cent, only slight penalty at 80 per cent, about 22 per cent at 50 per cent power factor and at zero power factor the rate would be based on a quantity just under one-third of the volt-amperes. At 60-deg phase displacement, for each 100 units of net power consumed, 122 units are delivered and 22 returned, yet the reactive volt-amperes are 173, the volt-amperes 200.

Average positive power may be measured directly or by the arithmetic addition of average negative power to average power. If evaluated by the latter method, comparatively rough measurements of the negative contribution would suffice unless the power factor is habitually low; especially is this statement true if the power factor is generally fairly high. Similar statements may be made in regard to average positive energy flow, average energy flow and average negative energy flow. Whatever the character of unbalance or of wave form the measurement procedure just outlined leads to measurable quantities of an unambiguous nature that seem well suited to commercial use. Negative power in its relations to positive power and average power represents a direct comparison of the actual activities in the circuit.

By contrast, reactive volt-amperes is the measure of a quantity that does not appear in the circuit as such but is only the coefficient of an arbitrarily chosen component of power pulsation and has dimensions and magnitude such that the equation $W^2 + S^2 = E^2I^2$ is satisfied. ($S$ = reactive volt-amperes. For complex waves $\Sigma\,[W_1^2 + W_3^2 + \ldots + S_1^2 + S_3^2 + \ldots] \overset{=}{<} E^2I^2$). It is a sort of complementary quantity useful in calculation. It connotes the defect that exists between actual and ideal utilization of the quantities of current and voltage appearing in the circuit.

In what has been said, there is no intention to disparage the use of reactive volt-ampere measurements as a means of determining kilovolt-amperes in the measurement of demand. This last quantity (kva) undoubtedly has its field of usefulness.

## CONCLUSIONS

1. Reactive volt-amperes are not to be identified with the coefficient of the sine term in the equation for instantaneous power.
2. Reactive volt-amperes is an assumed quantity, not a naturally occurring quantity.
3. It is related to average power through the product of the rms values of current and voltage.
4. Certain quantities having to do with the surging of real power have properties that commend further consideration from the viewpoint of commercial application.
5. When the current and voltage waves are purely sinusoidal, the quantities referred to in 4 have easily stated, though somewhat complicated, relationships to the more familiar quantities reactive volt-amperes, power factor, and reactive factor. When the wave forms are complex the relationships are very much involved.

## Appendix I

It is interesting to examine the power equation in a more general form.

$$e = E_{m1}\sin(\omega t - \varphi_1) + E_{m3}\sin(3\omega t - \varphi_3) + E_{m5}\sin(5\omega t - \varphi_5) + \ldots \qquad (20)$$

$$i = I_{m1}\sin(\omega t - \theta_1) + I_{m3}\sin(3\omega t - \theta_3) + I_{m5}\sin(5\omega t - \theta_5) + \ldots \qquad (21)$$

$$\begin{aligned} p = ei = {} & E_{m1}I_{m1}\sin(\omega t - \varphi_1)\sin(\omega t - \theta_1) \\ & + E_{m1}I_{m3}\sin(\omega t - \varphi_1)\sin(3\omega t - \theta_3) \qquad (22) \\ & + E_{m1}I_{m5}\sin(\omega t - \varphi_1)\sin(5\omega t - \theta_5) + \ldots \\ & + E_{m3}I_{m1}\sin(3\omega t - \varphi_3)\sin(\omega t - \theta_1) \\ & + E_{m3}I_{m3}\sin(3\omega t - \varphi_3)\sin(3\omega t - \theta_3) + \ldots \\ & + E_{m5}I_{m1}\sin(5\omega t - \varphi_5)\sin(\omega t - \theta_1) \\ & + E_{m5}I_{m3}\sin(5\omega t - \varphi_5)\sin(3\omega t - \theta_3) \\ & + E_{m5}I_{m5}\sin(5\omega t - \varphi_5)\sin(5\omega t - \theta_5) + \ldots \end{aligned}$$

$$\begin{aligned} = {} & \frac{E_{m1}I_{m1}}{2}[\cos(\varphi_1 - \theta_1) - \cos(\varphi_1 + \theta_1)\cos 2\omega t \\ & -\sin(\varphi_1 + \theta_1)\sin 2\omega t] + \frac{E_{m1}I_{m3}}{2}[\cos(\varphi_1 - \theta_3)\cos 2\omega t \\ & - \sin(\varphi_1 - \theta_3)\sin 2\omega t - \cos(\varphi_1 + \theta_3)\cos 4\omega t \\ & \quad - \sin(\varphi_1 + \theta_3)\sin 4\omega t] + \ldots \\ & + \frac{E_{m3}I_{m1}}{2}[\cos(\varphi_3 - \theta_1)\cos 2\omega t \\ & \quad + \sin(\varphi_3 - \theta_1)\sin 2\omega t - \cos(\varphi_3 + \theta_1)\cos 4\omega t \\ & \quad - \sin(\varphi_3 + \theta_1)\sin 4\omega t] \\ & \quad + \frac{E_{m3}I_{m3}}{2}[\cos(\varphi_3 - \theta_3) - \cos(\varphi_3 + \theta_3)\cos 6\omega t \\ & \quad - \sin(\varphi_3 + \theta_3)\sin 6\omega t] + \ldots \\ & \quad + \frac{E_{m5}I_{m1}}{2}[\cos(\varphi_5 - \theta_1)\cos 4\omega t \\ & + \sin(\varphi_5 - \theta_1)\sin 4\omega t - \cos(\varphi_5 + \theta_1)\cos 6\omega t \\ & \quad - \sin(\varphi_5 + \theta_1)\sin 6\omega t] \\ & + \frac{E_{m5}I_{m3}}{2}[\cos(\varphi_5 - \theta_3)\cos 2\omega t + \sin(\varphi_5 - \theta_3)\sin 2\omega t \\ & \quad - \cos(\varphi_5 + \theta_3)\cos 8\omega t \\ & - \sin(\varphi_5 + \theta_3)\sin 8\omega t] + \frac{E_{m5}I_{m5}}{2}[\cos(\varphi_5 - \theta_5) \\ & \quad - \cos(\varphi_5 + \theta_5)\cos 10\omega t \\ & - \sin(\varphi_5 + \theta_5)\sin 10\omega t] + \ldots \qquad (22a) \\ & + \ldots \\ & + \ldots \end{aligned}$$

$$\begin{aligned} P = {} & \frac{E_{m1}I_{m1}}{2}\cos(\varphi_1 - \theta_1) + \frac{E_{m3}I_{m3}}{2}\cos(\varphi_3 - \theta_3) \\ & + \frac{E_{m5}I_{m5}}{2}\cos(\varphi_5 - \theta_5) + \ldots \qquad (23) \end{aligned}$$

It may be observed that but few terms are involved in the evaluation of average power, but in the pulsation and storage of energy, products involving the fundamental and a large harmonic are of much more importance than those terms involving that harmonic alone.

With a purely resistance load, the resistance remaining constant through the cycle

$$\frac{E_1}{I_1} = \frac{E_3}{I_3} = \frac{E_5}{I_5} = \text{etc.}$$

In this case, many pairs of terms could be combined since $E_1I_3 = E_3I_1$, etc.

## Appendix II

### SIGN FOR REACTIVE VOLT-AMPERES

The proper sign of reactive volt-amperes caused by the presence of inductance in a circuit should emerge of itself from a consideration of the previously adopted conventions for fundamental quantities. These are:

1. The algebraic conventions for complex quantities and direction of rotation of time vectors.
2. Definition of impedance as

$$Z = R + jX$$

where $X$ is positive for an inductive reactance.

From these two it follows that admittance $Y$ is

$$Y = \frac{R}{Z^2} - j\frac{X}{Z^2}$$

Then power $P$ may be expressed either as

$$P = E^2Y = E^2\frac{R}{Z^2} - jE^2\frac{X}{Z^2}$$

or

$$P = I^2Z = I^2R + jI^2X$$

depending upon whether the voltage $E$ or the current $I$ is used as the original reference axis. Thus the sign of inductive reactive volt-amperes correctly may have either a negative or a positive sign but, to avoid confusion, one sign should be established arbitrarily.

The reasons which have led to the practice of plotting inductive reactive volt-amperes with a negative sign may be summarized as follows:

1. Counter-clockwise has been established as the positive direction of rotation for voltage, current, and other vector diagrams.
2. The great preponderance of multiple distribution involves a prevailing preference for a voltage reference vector (in voltage-current diagrams).
3. Since powers and reactive volt-amperes at equal voltages are proportional to the corresponding currents, it is desirable to have the corresponding diagrams recognizably similar, and the corresponding complex numbers with similar signs.
4. With counter-clockwise rotation and a voltage reference vector adopted, consistency requires that leading quantities be represented as counter-clockwise and lagging quantities as clockwise relative to the reference vector.
5. In all cases in which convenience dictates alternatives to the above arbitrary convention as, for example, a current reference vector, this may freely be done by clearly specifying the conventions substituted.
6. While theoretical reasons have been proposed to show why either one or the other of these conventions can logically be used, when these are examined carefully it does not appear that the argument on this basis can be made conclusive for either convention.

Articles appearing in contemporary literature show a surprising difference in point of view from which the sign of inductive reactive power may be determined and about an equal division between those favoring a negative sign and those opposed to it. However, it is recognized by all that an arbitrary convention is desirable and, since one convention may be applied as easily as the other mathematically, that one should be chosen which clearly is more advantageous from a practical standpoint.

### NOTES ON THE MEASUREMENT OF REACTIVE VOLT-AMPERES

(PRATT)

**L. A. Doggett:** The writer makes the following recommendations:

1. Considering the typical modern system, we agree on the assumption that there is but one type of reactive power, that associated with the storage and discharge of magnetic energy. On that basis a survey of the active and reactive power in the various parts of a system would yield a record somewhat as follows:

| | Survey | | | |
|---|---|---|---|---|
| | Receiving | | Supplying | |
| Part | Active power $I^2R$ | Reactive power $I^2X$ | Active power $I^2R$ | Reactive power $I^2X$ |
| .. | .. | .. | .. | .. |
| .. | .. | .. | .. | .. |

A synchronous motor either may receive or supply reactive power, thus defined. A static condenser always supplies reactive power. This recommendation is in agreement with the suggestions of Mr. J. A. Johnson.

2. As to the sign to be attached to reactive power of the magnetic type: consistency with the convention of counterclockwise rotation of vectors and with the conventions of polar coordinate analytical geometry calls for the *negative* sign in front of $jQ$, when $jQ$ represents reactive power of the magnetic type. This is

developed at length on pages 29-31 of the writer's "A-C Analysis by the $I^2R - I^2X - I^2Z$ Method." (Edwards Brothers, Inc., Ann Arbor, Michigan, 1933.)

3. Recommend for all cases, sinusoidal or otherwise that $\Sigma E_n I_n \sin \theta_n$ be made the standard definition for reactive power for both single phase and polyphase cases.

4. Recommend that in all cases the apparent power be defined as

$$\sqrt{\overline{\Sigma E_n I_n \cos \theta_n}^2 + \overline{\Sigma E_n I_n \sin \theta_n}^2}$$

which is not always the same as the product of the voltmeter and ammeter readings.

5. Recommend that power factor be defined as

$$\frac{\Sigma E_n I_n \cos \theta_n}{\text{apparent power}}$$

where apparent power is as defined in (**4**).

Note: These definitions obviate the necessity of the terms "fictitious power," "deforming power," and "distortion power."

On the basis of the foregoing definitions the writer has worked out a fairly complete analysis of a wide range of alternating current problems; also a great deal of experimental work with nonsinusoidal cases, all of which have led to the adoption of these definitions. They have been incorporated in the booklet in the foregoing reference. The validity of the law of conservation of reactive power as well as the law of the conservation of active power has become so well established in the writer's mind that it is applied here tentatively to the study of the mercury arc rectifier, with the results indicated in the following table.

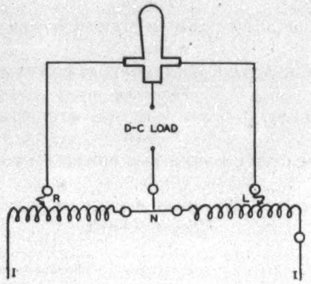

FIG. 1

TABLE I

| Item | $I^2R$ | $I^2X$ |
|---|---|---|
| (1)...Input | 891.2 | 157.5 |
| (2)...Output | 606.0 | |
| (3)...Arc | 180.0 | |
| (4)...Transformer | | |
| *RN* | 44.2 | 28.0 |
| *LN* | 35.6 | 28.0 |
| (5)...Transformer | | |
| *RI* | 20.3 | 28.0 |
| *LI* | 20.3 | 28.0 |
| (6)...Core loss | 3.0 | |
| Excitation | | 4.0 |
| (7)...Output + losses | 909.4 | 116.0* |

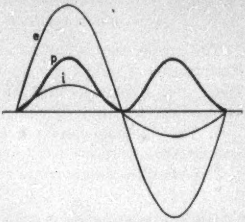
(1) By wave analysis up to and including the 7th harmonic.
$\Sigma I^2R = \Sigma (P_1 + P_3 + P_5 + P_7)$, also by wattmeter.
$\Sigma I^2X = \Sigma (Q_1 + Q_3 + Q_5 + Q_7)$.
(2) From oscillograms.
(3) From oscillograms, vacuum tube voltmeter, and wattmeter.
(4) $I^2X$ from $d/dt$ of $(\frac{1}{2}LI^2)$, where $L$ = the inductance of *RN*, *LN*.
(5) $I^2$ from oscillograms.

*Approximation in assuming $L$ constant for all types of current values and shapes.

These results were obtained by Mr. R. B. Tomlinson in connection with a Master's Degree thesis at the Pennsylvania State College. Oscillograms of all voltages and currents were taken. Fig. 1 shows the location of the oscillograph current vibrators; the letters apply to Table I.

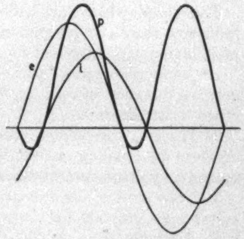
To sum up, the writer believes from experience that reactive power follows a law similar to the law for the conservation of energy. Professor C. D. Busila says that reactive power is not conserved in exchanges between circuits of different frequency, for example, between the rotor and the stator of the induction motor. With this statement the writer is not in agreement. This opinion is based on the erroneous assumption that the reactances of stator and rotor are separate entities. As a matter of fact, as brought out in Still's "Elements of Electrical Machine Design," 1932 Edition, pages 473-478, the reactance of an induction motor is 95 per cent or more associated with the stator. In the past it has been customary for convenience in transformer treatments of induction motors to split the reactance equally between stator and rotor.

FIG. 2—INSTANTANEOUS VALUES OF VOLTS, AMPERES, AND POWER FOR A PHASE ANGLE OF ZERO DEGREES BETWEEN VOLTAGE AND CURRENT. AVERAGE VALUE OF POWER IS $E_mI_m/2$. INSTANTANEOUS POWER IS PROPORTIONAL TO INSTANTANEOUS PHASE-TORQUE



**Frank W. Godsey, Jr.:** The half-formed idea in the minds of some operators that reactive power is a fictitious quantity representing a mathematical convenience is in error. Harmonic power fluctuations in single-phase circuits are increased with increases in phase displacement between current and voltage. With a fixed load, the demand upon flywheel and governor of the prime mover rises with increases in phase angle in order to maintain stability of operation. Maximum mechanical forces on windings, supports, and insulation rise; and supersynchronous torque variations in shafts and couplings increase, resulting in changes in load on bearings and fittings. (See Figs. 2 and 3.)

FIG. 3—INSTANTANEOUS VALUES OF VOLTS, AMPERES, AND POWER FOR A PHASE ANGLE OF 45 DEGREES BETWEEN VOLTAGE AND CURRENT. AVERAGE VALUE OF POWER IS $E_mI_m/2.828$. INSTANTANEOUS POWER IS PROPORTIONAL TO INSTANTANEOUS PHASE-TORQUE



Assuming a superposition principle and obtaining total voltamperes through a summation of the products of individual frequency components of the voltage multiplied by their respective current components, a true power factor as at present defined would be obtained by dividing power by total voltamperes. However, the only readily available measuring instruments give true power, effective volts, and effective amperes. Where only the current for instance, has harmonics as in a non-linear resistance load, the power factor may be unity. And yet as calculated from power factor = $P/EI$, the result always will be less than unity. Therefore, the old conception of power factor is too ponderous to use except in the special case of sine wave voltage and current.

It has been suggested that a distortion factor be applied in current, voltage, and power factor measurements to make possible a reconciliation with reactive power measurements. This again is a subterfuge that is applicable only in a specific case and under fixed conditions. A distortion factor is an added complication to an already confused situation.

Reactive power in single-phase circuits is readily measured with meters ordinarily available, and since the voltage waves in most circuits are very close to sine waves, the measured reactive power will not include any terms due to current harmonics as these will cancel out over a complete cycle. Therefore, the writer suggests that the term reactive power in single-phase circuits refer only to the fundamental frequency component of the reactive power, and that when both current and voltage waves have harmonics that the total reactive power component be called the total reactive power.

It appears that most of the difficulty in evaluating power factor lies in the attempt to carry over into the non-sinusoidal circuit the convenient relations existing in the special case of sinusoidal voltage and current waves. Since there can be no reconciliation between reactive power, true power, and power factor except in special cases, the obvious remedy is to abandon any attempt to make such a reconciliation.

Station operators dispatch real power and reactive power over a system, not power factor. The power salesman is very much interested in power factor because of the larger investment in operating plant required for low power factor loads and increased operating losses incidental to that condition; therefore power rates should be and are higher for low power factor loads. The user of power is interested in power factor for the same reasons as the power salesman, and has an incentive to watch load characteristics in order to take advantage of a lower rate.

Therefore, it appears that the only individuals interested in power factor calculations are the men who adjust power rates. Why not then, as referred to in Mr. Knowlton's review of the subject, banish power factor from the academic circle and change its definition in such a way that it fulfills all of the requirements of the rate adjusters without attempting to serve a post on the technical and operating staff? Reactive power and real power fill all the requirements of the mathematician and operator, and Fourier series describes non-sinusoidal voltages and currents accurately.

A reasonable solution would be to multiply the effective value of current by the effective value of voltage to obtain the maximum demand for plant investment. Dividing the real power measured in the circuit by this product would give a power factor = $P/E_{eff} \mathrm{x} I_{eff}$, which is a real measure of the customer's utilization of the operating plant demanded by his load. It has no significance with respect to reactive power except in special cases, and is not intended for any use except the evaluation of the utilization efficiency of a power consumer with respect to the operating plant required to supply the load. It is independent of "distortion factors" and reactive power measurements, but it is accurate in evaluating required plant investment and operating losses.

Going now to the case of polyphase systems, we find that for the balanced system with sine wave voltages and currents, the same conditions apply as in the single-phase case. Again, the writer suggests that reactive power refer only to the fundamental frequency component of the out-of-phase power; this is the value usually measured by rkva meters since voltage waves seldom have large harmonics. Let the entire out-of-phase component be known as the total reactive power as in the single-phase case; if a further description of a particular case is necessary, oscillograms must furnish it in almost every instance.

In calculating average power factor for a polyphase system, effective phase voltages should be multiplied by effective phase currents of the same frequency and the products added to obtain total kilovoltampere required of the generating plant. Dividing the total measured power by this sum gives power factor, which has no mathematical significance, but accurately expresses the plant utilization efficiency of the load and is a measure of line losses. In most industrial loads the voltage supplied by the power company is close enough to a sine wave that through the geometry of the circuit phase voltages are known after a few simple calculations.

The problem of metering such circuits is relatively simple since effective values of current and voltage are to be measured. Efficient thermo-couple instruments are available which will give correct results, and rectifier type meters may be used in the majority of cases to measure kilovoltampere without serious error. In the average polyphase system, it is sufficient to totalize all effective currents either in a thermal element, rectifier outputs, or some similar method, and the potential coil of the kilovoltampere meter is supplied through a rectifier in a suitable voltage phase to measure kilovoltampere.

Suggested changes are tabulated as follows:

### SINGLE PHASE

Reactive power—Fundamental frequency component of the out-of-phase power component.

Total reactive power—Total out-of-phase power component including the fundamental.

Power factor—Power divided by the product of effective volts by effective amperes, with no relation to reactive power except in special cases.

### POLYPHASE

Reactive power—Sum of fundamental frequency components of out-of-phase power components for all phases.

Total reactive power—Sum of total out-of-phase power components including the fundamentals for all phases.

Power factor—Total power divided by the sum of the individual products for the several phases of effective phase voltages by effective phase currents respectively, with no mathematical significance with respect to reactive power except in special cases.

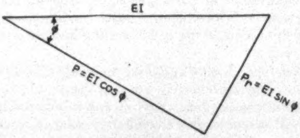


Fig. 4

**V. Karapetoff:** This discussion considers the problem of power factor from a purely practical point of view, namely that of feasible measurements in unbalanced polyphase industrial circuits. Any definition of power factor that cannot be realized with fairly simple practical measuring instruments will remain a dead letter; on the other hand, a definition that may not be quite rigorous theoretically may prove to be of great practical usefulness if the corresponding measurements are simple and can readily be understood by the average operating engineer.

To illustrate this proposal by a concrete example, consider a large three-phase arc furnace with the currents in the three phases not balanced and containing appreciable higher harmonics. Also assume for the sake of generality that the terminal voltages are somewhat distorted in magnitude and phase and are not quite sinusoidal. The neutral point will be assumed to be not accessible. Let a clause in the contract with the operating company prescribe a graduated penalty for low power factor. The question is to determine the average value of the power factor for a day, a melting cycle, a month, etc.

For a contrast, consider also a simple single-phase laboratory circuit consisting of a constant resistance and constant inductance in series and connected to a strictly sinusoidal source of voltage of constant magnitude and frequency. Let the nature of the circuit apparatus be such that the current also is strictly sinusoidal. The power relations are represented by the familiar triangle in Fig. 4, in which, by a commonly accepted definition, the power factor is equal to the cosine of the angle $\phi$. This triangle may be constructed by performing one of the following 6 sets of measurements:

| | | | |
|---|---|---|---|
| (1) | $E$, $I$, and $P$ | (4) | $\phi$, $E$, and $I$ |
| (2) | $E$, $I$, and $P_r$ | (5) | $\phi$ and $P$ |
| (3) | $P$ and $P_r$ | (6) | $\phi$ and $P_r$ |

In this table $E$ is the effective value of the terminal voltage, as read on a voltmeter, $I$ is the effective value of the current read on an ammeter, and $P$ is the average power read on an indicating wattmeter. $P_r$ is the so-called reactive power, read on the same wattmeter with the current in its potential winding "quadratured," that is, displaced by 90 degrees from its phase when measuring $P$. Reactive-power meters are used in practice, and methods for quadraturing the shunted current are well known. The angle $\phi$ is determined by means of a power-factor meter, of which there are several types on the market. The table simply gives the 6 ways in which the right-angle triangle in Fig. 4 may be constructed, knowing 2 of its parts. Assuming the instruments and the readings to be accurate, the same triangle will be obtained from any of the 6 combinations of data, and the theory involved is well understood by most operating engineers.

An irregular polyphase circuit, such as that of the above-mentioned arc furnace, has no intrinsic or scientific power factor. If for some practical reasons it seems desirable to introduce such a concept, it must largely be a matter of definition and agreement. Of course, the definition must be such that for a balanced sinusoidal $n$-phase circuit this definition will agree with that in Fig. 4, because such a symmetrical circuit may be split into $n$ independent identical single-phase circuits. Moreover, the practical requirement of averaging values over an appreciable interval of time, and sometimes of measuring the maximum demand as well, makes the use of integrating instruments mandatory.

Let us therefore consider again the foregoing table of 6 sets of measurements and ask ourselves which of these could be generalized for use with an arc furnace by means of integrating instruments. It will be seen at once that all the combinations involving $E$, $I$ or $\phi$ are less suitable or desirable, partly because of lack of proper instruments, and partly because we do not know what the "total volt-amperes" might be in such a circuit with higher harmonics and with an inaccessible neutral. This leaves the combination (3), with $P$ and $P_r$ to be measured by watt-hour meters. Measurement of $P$ is standard in practically every installation, leaving only the question of $P_r$ to be considered.

It is proposed for the purposes of defining and computing the value of the power factor on an unbalanced polyphase circuit, even with non-sinusoidal currents and voltages, that the reactive power or energy be defined as the reading of a polyphase wattmeter or watt-hour meter with its potential windings quadratured. By quadraturing in this case is meant providing such connections that the shunt currents actually would be shifted by 90 degrees in phase when the applied phase voltages become balanced. With unbalanced and unsymmetrical voltages the actual shift in phase may be different from 90 degrees. This, however, is foreseen in the above definition, the actual reading of the meter under such conditions being meant, without any change in connections or other compensation. With $P$ and $P_r$ reading directly on two integrating watt-hour meters, the triangle in Fig. 4 becomes determined, thus making it possible to compute the "equivalent" values of the angle $\phi$ and the total volt-amperes $EI$. The simple practical procedure would be to determine $\tan \phi = P_r/P$, and to find the corresponding $\cos \phi$ from trigonometric tables, without constructing the triangle. For various practical methods of quadraturing meters see, for example, the writer's "Experimental Electrical Engineering," Third Edition, Vol. II, pp. 139-143.
